RECOMMENDED PRACTICE
DNV-RP-C203

FATIGUE DESIGN OF
OFFSHORE STEEL STRUCTURES

APRIL 2010
FOREWORD

DET NORSKE VERITAS (DNV) is an autonomous and independent foundation with the objectives of safeguarding life, property and the environment, at sea and onshore. DNV undertakes classification, certification, and other verification and consultancy services relating to quality of ships, offshore units and installations, and onshore industries worldwide, and carries out research in relation to these functions.

DNV Offshore Codes consist of a three level hierarchy of documents:

— *Offshore Service Specifications.* Provide principles and procedures of DNV classification, certification, verification and consultancy services.

— *Offshore Standards.* Provide technical provisions and acceptance criteria for general use by the offshore industry as well as the technical basis for DNV offshore services.

— *Recommended Practices.* Provide proven technology and sound engineering practice as well as guidance for the higher level Offshore Service Specifications and Offshore Standards.

DNV Offshore Codes are offered within the following areas:

A) Qualification, Quality and Safety Methodology
B) Materials Technology
C) Structures
D) Systems
E) Special Facilities
F) Pipelines and Risers
G) Asset Operation
H) Marine Operations
J) Cleaner Energy
O) Subsea Systems

Amendments and Corrections

This document is valid until superseded by a new revision. Minor amendments and corrections will be published in a separate document normally updated twice per year (April and October).

For a complete listing of the changes, see the “Amendments and Corrections” document located at: http://webshop.dnv.com/global/, under category “Offshore Codes”.

The electronic web-versions of the DNV Offshore Codes will be regularly updated to include these amendments and corrections.
General
This document supersedes DNV-RP-C203, April 2008.

Main changes April 2010

- Information on standard deviation in the S-N curves is included.
- A modified S-N curve for small diameter umbilicals is included.
- The section on qualification of new S-N curves is extended. Some guidance on assessment of a design S-N curve based on a limited number of test data is given.
- A new section on requirements to NDE and acceptance criteria is included.
- The section on stress concentration factors for square to square joints is revised.
- A new section on analysis of connectors is included.
- The section on stress concentration factors for girth welds in tubular sections and pipelines is extended with examples of practical use in the commentary section.
- A more clear definition of nominal stresses in pipes and pipelines is made.

- Some new expressions for stress concentration factors for tubular T-joints in frame structures are included that are considered to reduce engineering work and improve the reliability of fatigue analysis.
- The section on fatigue assessment of penetrations in plated structures is extended and made more general for purpose of combining capacity assessment with finite element analysis where penetrations are not part of the finite element model.
- The section on requirements to grinding for fatigue life improvement is extended.
- A section on low cycle fatigue in combination with high cycle fatigue is included in the commentary section.
- The reference list is revised and new references are included.
- Some text has been revised to improve readability.

1. Introduction

1.1 General

This Recommended Practice presents recommendations in relation to fatigue analyses based on fatigue tests and fracture mechanics. Conditions for the validity of the Recommended Practice are given in section 1.2.

The aim of fatigue design is to ensure that the structure has an adequate fatigue life. Calculated fatigue lives also form the basis for efficient inspection programmes during fabrication and the operational life of the structure.

To ensure that the structure will fulfill its intended function, a fatigue assessment, supported where appropriate by a detailed fatigue analysis, should be carried out for each individual member, which is subjected to fatigue loading. See also section 2.11. It should be noted that any element or member of the structure, every welded joint and attachment or other form of stress concentration, is potentially a source of fatigue cracking and should be individually considered.

1.2 Validity of standard

1.2.1 Material

This Recommended Practice is valid for steel materials in air with yield strength less than 960 MPa. For steel materials in seawater with cathodic protection or steel with free corrosion the Recommended Practice is valid up to 550 MPa.

This Recommended Practice is also valid for bolts in air environment or with protection corresponding to that condition of grades up to 10.9, ASTM A490 or equivalent.

This Recommended Practice may be used for stainless steel.

1.2.2 Temperature

This Recommended Practice is valid for material temperatures of up to 100°C. For higher temperatures the fatigue resistance data may be modified with a reduction factor given as:

\[ R_T = 0.10376 - 0.239 \cdot 10^{-3} T - 1.372 \cdot 10^{-6} T^2 \]  \hspace{1cm} (1.2.1)

where \( T \) is given in °C (Derived from figure in IIW document XII-1965-03/XV-1127-03). Fatigue resistance is understood to mean strength capacity. The reduced resistance in the S-N curves can be derived by a modification of the \( \log \pi \) as:

\[ \log \bar{a}_{gr} = \log \bar{a} + m \log R_f \]  \hspace{1cm} (1.2.2)

1.2.3 Low cycle and high cycle fatigue

This Recommended Practice has been produced with the purpose of assessing fatigue damage in the high cycle region. See also Appendix D, Commentary.

1.3 Methods for fatigue analysis

The fatigue analysis should be based on S-N data, determined by fatigue testing of the considered welded detail, and the linear damage hypothesis. When appropriate, the fatigue analysis may alternatively be based on fracture mechanics. If the fatigue life estimate based on S-N data is short for a component where a failure may lead to severe consequences, a more accurate investigation considering a larger portion of the structure, or a fracture mechanics analysis, should be performed. For calculations based on fracture mechanics, it should be documented that there is a sufficient time interval between time of crack detection during in-service inspection and the time of unstable fracture.

All significant stress ranges, which contribute to fatigue damage, should be considered. The long term distribution of stress ranges may be found by deterministic or spectral analysis, see also ref. 1/1. Dynamic effects shall be duly accounted for when establishing the stress history. A fatigue analysis may be based on an expected stress history, which can be defined as expected number of cycles at each stress range level during the predicted life span. A practical application of this is to establish a long term stress range history that is on the safe side. The part of the stress range history contributing most significantly to the fatigue damage should be most carefully evaluated. See also Appendix D, Commentary, for guidance.

It should be noted that the shape parameter \( h \) in the Weibull distribution has a significant impact on calculated fatigue damage. For effect of the shape parameter on fatigue damage see also design charts in Figure 5-1 and Figure 5-2. Thus, when the fatigue damage is calculated based on closed form solutions with an assumption of a Weibull long term stress range distribution, a shape parameter to the safe side should be used.

1.4 Definitions

Classified structural detail: A structural detail containing a structural discontinuity including a weld or welds, for which the nominal stress approach is applicable, and which appear in the tables of this Recommended Practice. Also referred to as standard structural detail.

Constant amplitude loading: A type of loading causing a regular stress fluctuation with constant magnitudes of stress maxima and minima.

Crack propagation rate: Amount of crack propagation during one stress cycle.

Crack propagation threshold: Limiting value of stress intensity factor range below which the stress cycles are considered to be non-damaging.

Eccentricity: Misalignment of plates at welded connections measured transverse to the plates.

Effective notch stress: Notch stress calculated for a notch with a certain effective notch radius.

Fatigue deterioration of a component caused by crack initiation and/or the growth of cracks.

Fatigue action: Load effect causing fatigue.

Fatigue damage ratio: Ratio of fatigue damage at considered number of cycles and the corresponding fatigue life at constant amplitude loading.

Fatigue life: Number of stress cycles at a particular magnitude required to cause fatigue failure of the component.

Fatigue limit: Fatigue strength under constant amplitude loading corresponding to a high number of cycles large enough to be considered as infinite by a design code.

Fatigue resistance: Structural detail’s resistance against fatigue actions in terms of S-N curve or crack propagation properties.

Fatigue strength: Magnitude of stress range leading to particular fatigue life.

Fracture mechanics: A branch of mechanics dealing with the behaviour and strength of components containing cracks.

Design Fatigue Factor: Factor on fatigue life to be used for design.

Geometric stress: See “hot spot stress”.

Hot spot: A point in structure where a fatigue crack may initiate due to the combined effect of structural stress fluctuation and the weld geometry or a similar notch.

Hot spot stress: The value of structural stress on the surface at the hot spot (also known as geometric stress or structural stress).

Local nominal stress: Nominal stress including macro-geometric effects, concentrated load effects and misalignments, disregarding the stress raising effects of the welded joint itself.
**Local notch**: A notch such as the local geometry of the weld toe, including the toe radius and the angle between the base plate surface and weld reinforcement. The local notch does not alter the structural stress but generates non-linear stress peaks.

**Macro-geometric discontinuity**: A global discontinuity, the effect of which is usually not taken into account in the collection of standard structural details, such as large opening, a curved part in a beam, a bend in flange not supported by diaphragms or stiffeners, discontinuities in pressure containing shells, eccentricity in lap joints.

**Macro-geometric effect**: A stress raising effect due to macro-geometry in the vicinity of the welded joint, but not due to the welded joint itself.

**Membrane stress**: Average normal stress across the thickness of a plate or shell.

**Miner sum**: Summation of individual fatigue damage ratios caused by each stress cycle or stress range block according to Palmgren-Miner rule.

**Misalignment**: Axial and angular misalignments caused either by detail design or by fabrication.

**Nominal stress**: A stress in a component, resolved, using general theories such as beam theory.

**Nonlinear stress peak**: The stress component of a notch stress which exceeds the linearly distributed structural stress at a local notch.

**Notch stress**: Total stress at the root of a notch taking into account the stress concentration caused by the local notch. Thus the notch stress consists of the sum of structural stress and non-linear stress peak.

**Notch stress concentration factor**: The ratio of notch stress to structural stress.

**Paris’ law**: An experimentally determined relation between crack growth rate and stress intensity factor range.

**Palmgren-Miner rule**: Fatigue failure is expected when the Miner sum reaches unity. Reference is also made to Chapter 9 on uncertainties.

**Rainflow counting**: A standardised procedure for stress range counting.

**Shell bending stress**: Bending stress in a shell or plate like part of a component, linearly distributed across the thickness as assumed in the theory of shells.

**S-N curve**: Graphical presentation of the dependence of fatigue life (N) on fatigue strength (S).

**Stress cycle**: A part of a stress history containing a stress maximum and a stress minimum.

**Stress intensity factor**: Factor used in fracture mechanics to characterise the stress at the vicinity of a crack tip.

**Stress range**: The difference between stress maximum and stress minimum in a stress cycle.

**Stress range block**: A part of a total spectrum of stress ranges which is discretized in a certain number of blocks.

**Stress range exceedances**: A tabular or graphical presentation of the cumulative frequency of stress range exceedances, i.e. the number of ranges exceeding a particular magnitude of stress range in stress history. Here frequency is the number of occurrences.

**Stress ratio**: Ratio of minimum to maximum value of the stress in a cycle.

**Structural discontinuity**: A geometric discontinuity due to the type of welded joint, usually found in tables of classified structural details. The effects of a structural discontinuity are (i) concentration of the membrane stress and (ii) formation of secondary bending stress.

**Structural stress**: A stress in a component, resolved taking into account the effects of a structural discontinuity, and consisting of membrane and shell bending stress components. Also referred to as geometric stress or hot spot stress.

**Structural stress concentration factor**: The ratio of hot spot (structural) stress to local nominal stress. In this RP the shorter notation: “Stress concentration factor” (SCF) is used.

**Variable amplitude loading**: A type of loading causing irregular stress fluctuation with stress ranges (and amplitudes) of variable magnitude.

2. Fatigue Analysis Based on S-N Data

2.1 Introduction

The main principles for fatigue analysis based on fatigue tests are described in this section. The fatigue analysis may be based on nominal S-N curves for plated structures when appropriate. Additional stresses resulting from fabrication tolerances for butt welds and cruciform joints should be considered when the fabrication tolerances exceed that inherent the S-N data. Reference is made to sections 3.1 and 3.3.

When performing finite element analysis for design of plated structures it is often found more convenient to extract hot spot stress from the analysis than that of a nominal stress. Guidance on finite element modelling and hot spot stress derivation is presented in section 4.3. The calculated hot spot stress is then entered a hot spot S-N curve for derivation of cycles to failure. Also here additional stresses resulting from fabrication tolerances for butt welds and cruciform joints should be considered.

For design of simple tubular joints it is standard practice to use parametric equations for derivation of stress concentration factors to obtain hot spot stress for the actual geometry. Then this hot spot stress is entered a relevant hot spot S-N curve for tubular joints.

Results from performed fatigue analyses are presented in section 5 in terms of design charts that present allowable stresses as function of the Weibull shape parameter. The basis for the design charts is that long term stress ranges can be described by a two parameter Weibull distribution. The procedure can be used for different design lives, different Design Fatigue Factors and different plate thickness.

The following fatigue cracking failure modes are considered in this document (see also Figure 2-1):

- **Fatigue crack growth from the weld toe into the base material.**
  In welded structures fatigue cracking from weld toes into the base material is a frequent failure mode. The fatigue crack is initiated at small defects or undercuts at the weld toe where the stress is highest due to the weld notch geometry. A large amount of the content in this RP is made with the purpose of achieving a reliable design with respect to this failure mode.

- **Fatigue crack growth from the weld root through the fillet weld.**
  Fatigue cracking from root of fillet welds with a crack growth through the weld is a failure mode that can lead to significant consequences. Use of fillet welds should be sought avoided in connections where the failure consequences are large due to less reliable NDE of this type of connection compared with a full penetration weld. However, in some welded connections use of fillet welds can hardly be avoided and it is also efficient for fabrication. The specified design procedure in this document is considered to provide reliable connections also for fillet welds.

- **Fatigue crack growth from the weld root into the section under the weld.**
  Fatigue crack growth from the weld root into the section under the weld is observed during service life of structures in laboratory fatigue testing. The number of cycles to failure for this failure mode is of a similar magnitude as fatigue cracking from the weld toe in as welded condition. There is no methodology that can be recommended used to avoid this failure mode except from using alternative types of welds locally. This means that if fatigue life improvement of the weld toe is required the connection will become more highly utilised and it is also required to make improvement for the root. This can be performed using a full penetration weld along some distance of the stiffener nose.

- **Fatigue crack growth from a surface irregularity or notch into the base material.**
  Fatigue cracking in the base material is a failure mode that is of concern in components with high stress cycles. Then the fatigue cracks often initiate from notches or grooves in the components or from small surface defects/irregularities. The specified design procedure in this document is considered to provide reliable connections also with respect to this failure mode.

![Figure 2-1](image-url)
c) Fatigue crack growth from the weld root into the section under the weld

d) Fatigue crack growth from a surface irregularity or notch into the base material

**Figure 2-1**
Explanation of different fatigue failure modes

### 2.2 Fatigue damage accumulation

The fatigue life may be calculated based on the S-N fatigue approach under the assumption of linear cumulative damage (Palmgren-Miner rule).

When the long-term stress range distribution is expressed by a stress histogram, consisting of a convenient number of constant stress range blocks \( \Delta \sigma_i \) each with a number of stress repetitions \( n_i \), the fatigue criterion reads:

\[
D = \frac{1}{k} \sum_{i=1}^{k} \eta \left( \frac{n_i}{N_i} \right) \leq \eta
\]

(2.2.1)

where

- \( D \) = accumulated fatigue damage
- \( \eta = \frac{1}{\text{Design Fatigue Factor from OS-C101 Section 6 Fatigue Limit States}} \)
- \( \bar{N} \) = intercept of the design S-N curve with the log N axis
- \( m \) = negative inverse slope of the S-N curve
- \( k \) = number of stress blocks
- \( n_i \) = number of stress cycles in stress block \( i \)
- \( N_i \) = number of cycles to failure at constant stress range \( \Delta \sigma_i \)
- \( \eta \) = usage factor

Applying a histogram to express the stress distribution, the number of stress blocks, \( k \), should be large enough to ensure reasonable numerical accuracy, and should not be less than 20. Due consideration should be given to selection of integration method as the position of the integration points may have a significant influence on the calculated fatigue life dependent on integration method.

See also section 5 for calculation of fatigue damage using design charts.

Reference is made to commentary section for derivation of fatigue damage calculated from different processes.

### 2.3 Fatigue analysis methodology and calculation of Stresses

#### 2.3.1 General

Fatigue analysis may be based on different methodologies depending on what is found most efficient for the considered structural detail. Different concepts of S-N curves are developed and referred to in the literature and in this RP. It is thus important that the stresses are calculated in agreement with the definition of the stresses to be used together with a particular S-N curve. Three different concepts of S-N curves are defined:

- Nominal stress S-N curve that is described in section 2.3.2.
- Hot spot stress S-N curve that is described in section 2.3.3 for plated structures and in section 2.3.4 for tubular joints.
- Notch stress S-N curve that is not used in the main part of this RP. (A notch stress S-N curve is listed in the commentary that can be used together with finite element analysis where the local notch is modelled by an equivalent radius. This approach is foreseen used only in special cases where it is found difficult to reliably assess the fatigue life using other methods).

Nominal stress is understood to be a stress in a component that can be derived by classical theory such as beam theory. In a simple plate specimen with an attachment as shown in Figure 4-1 the nominal stress is simply the membrane stress that is used for plotting of the S-N data from the fatigue testing. An example of fatigue design using this procedure is shown in the commentary section (Example with fatigue analysis of a drum).

Hot spot stress is understood to be the geometric stress created by the considered detail. (The notch stress due to the local weld geometry is excluded from the stress calculation as it is assumed to be accounted for in the corresponding hot spot S-N curve. The notch stress is defined as the total stress resulting from the geometry of the detail and the non-linear stress field due to the notch at the weld toe).

Derivation of stresses to be used together with the different S-N curves are described in more detail in the following section.

The procedure for the fatigue analysis is based on the assumption that it is only necessary to consider the ranges of cyclic stresses in determining the fatigue endurance (i.e. mean stresses are neglected for fatigue assessment of welded connections).

#### 2.3.2 Plated structures using nominal stress S-N curves

The joint classification and corresponding S-N curves takes into account the local stress concentrations created by the joints themselves and by the weld profile. The design stress can therefore be regarded as the nominal stress, adjacent to the weld under consideration. However, if the joint is situated in a region of stress concentration resulting from the gross shape of the structure, this must be taken into account. As an example, for the weld shown in Figure 2-2 a), the relevant local stress for fatigue design would be the tensile stress, \( \sigma_{\text{nominal}} \). For the weld shown in Figure 2-2 b), the stress concentration factor for the global geometry must in addition be accounted for, giving the relevant local stress equal to \( \text{SCF} \sigma_{\text{nominal}} \), where SCF is the stress concentration factor due to the hole. Thus the local
stress is derived as

\[ \sigma_{\text{local}} = \text{SCF} \sigma_{\text{nominal}} \]  

(2.3.1)

\( \sigma_{\text{local}} \) shall be used together with the relevant S-N curves D through G, dependent on joint classification.

The maximum principal stress is considered to be a significant parameter for analysis of fatigue crack growth. When the principal stress direction is different from that of the normal to the weld toe, it becomes conservative to use the principle stress range together with a classification of the connection for stress range normal to the weld toe as shown in Figure 2-3. As the angle between the principal stress direction and the normal to the weld, \( \phi \), is increased further, fatigue cracking may no longer initiate along the weld toe, but may initiate in the weld and grow normal to the principal stress direction as shown in Figure 2-4. This means that the notch at the weld toe does no longer significantly influence the fatigue capacity and a higher S-N curve applies for this stress direction.

More guidance on this for use of nominal S-N curves is presented in commentary D.4 Comm. 2.3.2 Plated structures using nominal stress S-N curves.

2.3.3 Plated structures using hot spot stress S-N curves

For detailed finite element analysis of welded plate connections other than tubular joints it may also be convenient to use the alternative hot spot stress for fatigue life assessment, see section 4.3 for further guidance. A relation between nominal stress and hot spot stress may be defined as

\[ \sigma_{\text{hot spot}} = \text{SCF} \sigma_{\text{nominal}} \]  

(2.3.2)

where SCF is structural stress concentration factor normally denoted as stress concentration factor.

The effect of stress direction relative to the weld toe as shown in Figures 2-3 and 2-4 when using finite element analysis and hot spot stress S-N curve is presented in section 4.3.4.

2.3.4 Tubular joints

For a tubular joint, i.e. brace to chord connection, the stress to be used for design purpose is the range of idealised hot spot stress defined by: the greatest value of the extrapolation of the maximum principal stress distribution immediately outside the region effected by the geometry of the weld. The hot spot stress to be used in combination with the T-curve is calculated as

\[ \sigma_{\text{hot spot}} = \text{SCF} \sigma_{\text{nominal}} \]  

(2.3.3)

where

\( \text{SCF} = \) stress concentration factor as given in section 3.3.

---

Figure 2-2
Explanation of local stresses
2.3.5 Fillet welds

The relevant stress range for potential cracks in the weld throat of load-carrying fillet-welded joints and partial penetration welded joints may be calculated as:

$$\Delta \sigma_w = \sqrt{\Delta \sigma^2 + \Delta \tau^2 + 0.2 \Delta \tau^2}$$  \hspace{1cm} (2.3.4)

where the stress components are explained in Figure 2-5.

The total stress fluctuation (i.e. maximum compression and maximum tension) should be considered to be transmitted through the welds for fatigue assessments.

2.3.6 Fillet welded bearing supports

Where support platting below bearings are designed with fillet welded connection, it should be verified that fatigue cracking of the weld will not occur. Even though the joint may be required to carry wholly compressive stresses and the plate surfaces may be machined to fit, the total stress fluctuation should be considered to be transmitted through the welds for fatigue assessment.

If it is assumed that compressive loading is transferred through contact, it should be verified that the contact will not be lost during the welding. The actual installation condition including maximum construction tolerances should be accounted for.

2.4 S-N curves

2.4.1 General

The fatigue design is based on use of S-N curves, which are obtained from fatigue tests. The design S-N curves which follow are based on the mean-minus-two-standard-deviation curves for relevant experimental data. The S-N curves are thus associated with a 97.7% probability of survival.

2.4.2 Failure criterion inherent the S-N curves

Most of the S-N data are derived by fatigue testing of small specimens in test laboratories. For simple test specimens the testing is performed until the specimen has failed. In these specimens there is no possibility for redistribution of stresses during crack growth. This means that most of the fatigue life is associated with growth of a small crack that grows faster as the crack size increases until fracture.

For details with the same calculated damage, the initiation period of a fatigue crack takes longer time for a notch in base material than at a weld toe or weld root. This also means that with a higher fatigue resistance of the base material compared with welded details, the crack growth will be faster in base material when fatigue cracks are growing.

For practical purpose one defines these failures as being crack growth through the thickness.

When this failure criterion is transferred into a crack size in a real structure where some redistribution of stress is more likely, this means that this failure criterion corresponds to a crack size that is somewhat less than the plate thickness.

The tests with tubular joints are normally of a larger size. These joints also show a larger possibility for redistribution of stresses as a crack is growing. Thus a crack can grow through the thickness and also along a part of the joint before a fracture occurs during the testing. The number of cycles at a crack size through the thickness is used when the S-N curves are derived. As these tests are not very different from that of the actual behaviour in a structure, this failure criterion for S-N curves for tubular corresponds approximately to the thickness at the hot spot (chord or brace as relevant).

2.4.3 S-N curves and joint classification

For practical fatigue design, welded joints are divided into several classes, each with a corresponding design S-N curve. All tubular joints are assumed to be class T. Other types of joint, including tube to plate, may fall in one of the 14 classes specified in Table 2-1, Table 2-2 and Table 2-3, depending upon:

- the geometrical arrangement of the detail
- the direction of the fluctuating stress relative to the detail
- the method of fabrication and inspection of the detail.

Each construction detail at which fatigue cracks may potentially develop should, where possible, be placed in its relevant joint class in accordance with criteria given in Appendix A. It should be noted that, in any welded joint, there are several locations at which fatigue cracks may develop, e.g. at the weld toe in each of the parts joined, at the weld ends, and in the weld...
itself. Each location should be classified separately.
The basic design S-N curve is given as

$$\log N = \log \bar{\sigma} - m \log \Delta \sigma$$  \hspace{1cm} (2.4.1)

$N$ = predicted number of cycles to failure for stress range $\Delta \sigma$
$\Delta \sigma$ = stress range
$m$ = negative inverse slope of S-N curve
$\log \bar{\sigma}$ = intercept of log N-axis by S-N curve

$$\log \bar{\sigma} = \log a - s_{\log N}$$  \hspace{1cm} (2.4.2)

where

$\log a$ = Intercept of mean S-N curve with the log N axis
$s_{\log N}$ = standard deviation of log N. Reference is made to Appendix D, Commentary.

The fatigue strength of welded joints is to some extent dependent on plate thickness. This effect is due to the local geometry of the weld toe in relation to thickness of the adjoining plates. See also effect of profiling on thickness effect in section 7.2. It is also dependent on the stress gradient over the thickness. Reference is made to Appendix D, Commentary. The thickness effect is accounted for by a modification on stress such that the design S-N curve for thickness larger than the reference thickness reads:

$$\log N = \log \bar{\sigma} - m \log \left( \frac{\Delta \sigma}{t_{ref}} \right)^k$$  \hspace{1cm} (2.4.3)

where

$m$ = negative inverse slope of the S-N curve
$\log \bar{\sigma}$ = intercept of log N axis
$t_{ref}$ = reference thickness equal 25 mm for welded connections other than tubular joints. For tubular joints the reference thickness is 32 mm. For bolts $t_{ref} = 25$ mm

The thickness exponent is included in the design equation to account for a situation that the actual size of the structural component considered is different in geometry from that the S-N data are based on. The thickness exponent is considered to account for different size of plate through which a crack will most likely grow. To some extent it also accounts for size of weld and attachment. However, it does not account for weld length or length of component different from that tested such as e.g. design of mooring systems with a significant larger number of chain links in the actual mooring line than what the test data are based on. Then the size effect should be carefully considered using probabilistic theory to achieve a reliable design, see Appendix D, Commentary.

2.4.4 S-N curves in air

S-N curves for air environment are given in Table 2-1 and Figure 2-6. The $T$ curve is shown in Figure 2-8.

In the low cycle region (less than $10^7$ cycles) the maximum stress range is that of the $B1$ curve as shown in Figure 2-6. However, for offshore structures subjected to typical wave and wind loading the main contribution to fatigue damage is in the region $N > 10^6$ cycles and the bilinear S-N curves defined in Table 2-1 can be used.

2.4.6 S-N curves for tubular joints

S-N curves for tubular joints in air environment and in seawater with cathodic protection are given in Table 2-1, Table 2-2 and Table 2-3.

Figure 2-8
S-N curves for tubular joints in air and in seawater with cathodic protection
2.4.7 S-N curves for cast nodes

It is recommended to use the C curve for cast nodes. Tests may give a more optimistic curve. However, the C curve is recommended in order to allow for weld repairs after possible casting defects and possible fatigue cracks after some service life. The probability of a repair during service life depends on accumulated fatigue damage. Reference is made to section 9.1 and Figure 9-3 which indicates fatigue failure probability as function of Design Fatigue Factor.

For cast nodes a reference thickness $t_{ref} = 38 \text{ mm}$ may be used provided that any possible repair welds have been ground to a smooth surface.

For cast nodes with a stress gradient over the thickness a reduced effective thickness may be used for assessment of thickness effect. The effective thickness to be used in equation (2.4.3) can be calculated as:

$$t_e = t_{actual} \left( \frac{S_0}{S_i} \right)^{1/k} \tag{2.4.4}$$

Where

- $S_0$ = hot spot stress on surface
- $S_i$ = stress 38 mm below the surface, under the hot spot
- $t_{actual}$ = thickness of cast piece at considered hot spot measured normal to the surface
- $t_e$ = effective thickness. $t_e$ shall not be less than 38 mm.
- $k$ = thickness exponent = 0.15

2.4.8 S-N curves for forged nodes

For forged nodes the B1 curve may be used for nodes designed with a Design Fatigue Factor equal to 10. For designs with DFF less than 10 it is recommended to use the C-curve to allow for weld repair if fatigue cracks should occur during service life.

2.4.9 S-N curves for free corrosion

S-N curves for free corrosion, i.e., without corrosion protection, are given in Table 2-3. See also Commentary section for consideration of corrosion protection of connections in the splash zone and inside tanks in FPSOs.

2.4.10 S-N curves for base material of high strength steel

The fatigue capacity of the base material is depending on the surface finish of the material and the yield strength.

For high strength steel other than cast steel with yield strength above 500 MPa and a surface roughness equal $R_{az} = 3.2$ or better the following design S-N curve can be used for fatigue assessment of the base material:

$$\log N = 17.446 - 4.70 \log \Delta \sigma \tag{2.4.5}$$

In air a fatigue limit at $2 \cdot 10^6$ cycles at a stress range equal 235 MPa can be used. For variable amplitude loading with one stress range larger than this fatigue limit a constant slope S-N curve should be used. Reference is also made to section 2.11.

For seawater with cathodic protection a constant slope S-N curve should be used. (The same as for air to the left of $2 \cdot 10^6$ cycles, see Figure 2-9). If requirements to yield strength, surface finish and corrosion protection are not met the S-N curves presented in sections 2.4.4, 2.4.5 and 2.4.9 should be used. The thickness exponent $k = 0$ for this S-N curve.

**Figure 2-9**

S-N curve for high strength steel (HS – curve)

2.4.11 S-N curves for stainless steel

For Duplex and for Super Duplex steel one may use the same classification as for C-Mn steels. Also for austenitic steel one may use the same classification as for C-Mn steels.

2.4.12 S-N curves for small diameter umbilicals

For fatigue design of small diameter pipe umbilicals (outer diameter in the range 10 -100 mm) made of super duplex steel with a yield strength larger than 500 MPa with thicknesses in the range 1.0 to 10 mm the following S-N curve can be used for fatigue assessment:

For $N \leq 10^7$:

$$\log N = 15.301 - 4.0 \log \left( \frac{1}{t_{ref}} \right)^{0.25}$$

and for $N > 10^7$:

$$\log N = 17.376 - 5.0 \log \left( \frac{1}{t_{ref}} \right)^{0.25} \tag{2.4.6}$$

where

- $t$ = actual thickness of the umbilical
- $t_{ref} = 1.0 \text{ mm}$
A normal good fabrication of the umbilicals is assumed as basis for this design S-N curve. The welds on the inside and outside of the pipes should show a smooth transition from the weld to the base material without notches and/or undercuts. A detailed NDE inspection for each connection is assumed.

The NDE methods are visual inspection and X-ray. For single pass welds, no indications are acceptable. For multipass welds the acceptance criteria shall be according to ASME B31.3, chapter IX high pressure service girth groove. Dye penetrant shall be used as a surface test in addition to visual inspection when relevant indications, as defined by ASME VIII div. 1, app.4. are found by X-ray.

The S-N curve is based on fatigue testing of specimens subjected to a mean stress up to 450 MPa.

The given S-N curve is established from test specimens that are not prestrained from reeling. However, based on a few test data with prestrained specimens it is considered acceptable to use the S-N curve also for umbilicals that have been reeled. Thus this S-N curve applies also when number of cycles under reeling is less than 10 and strain range during reeling is less than 2%.

The following design S-N curve can be used for the base material of umbilical tubes:

\[ \text{For } N \leq 10^7 : \]
\[ \log N = 15.301 - 4.0 \log \Delta \sigma \]
\[ \text{and for } N > 10^7 \]
\[ \log N = 17.376 - 5.0 \log \Delta \sigma \]

2.5 Mean stress influence for non welded structures

For fatigue analysis of regions in the base material not significantly affected by residual stresses due to welding, the stress range may be reduced if part of the stress cycle is in compression.

This reduction may e.g. be carried out for cut-outs in the base material. The calculated stress range obtained may be multiplied by the reduction factor \( f_m \) as obtained from Figure 2-11 before entering the S-N curve.

The reduction factor can be derived from the following equation

\[ f_m = \frac{\sigma_t + 0.6 \sigma_c}{\sigma_t + \sigma_c} \]

where

- \( \sigma_t \) = maximum tension stress
- \( \sigma_c \) = maximum compression stress
2.6 Effect of fabrication tolerances

Normally larger fabrication tolerances are allowed in real structures than that accounted for in the test specimens used to derive S-N data, ref. DNV OS-C401; Fabrication and Testing of Offshore Structures. Therefore, additional stresses resulting from normal fabrication tolerances should be included in the fatigue design. Special attention should be given to the fabrication tolerances for simple butt welds in plates and tubulars as these give the most significant increase in additional stress. Stress concentration factors for butt welds are given in section 3.1.2 and at tubular circumferential welds in section 3.3.7.

2.7 Requirements to NDE and acceptance criteria

Reference is made to DNV-OS-C401 Fabrication and Testing of Offshore Structures for requirements to non-destructive examination (NDE). Reference is also made to DNV-OS-C401 with respect to acceptance criteria. Some acceptance criteria related to the different classification of structural details are also presented in Appendix A.

For umbilical pipes requirements to NDE are presented in section 2.4.12. For partial penetration welds requirements to NDE are presented in section 2.8.

In general the requirements to NDE and acceptance criteria are being increased when going from the lower to the high level S-N curves. This should also be considered when designing connections showing a high fatigue utilisation.

2.8 Design chart for fillet and partial penetration welds

Design should be performed such that fatigue cracking from the root is less likely than from the toe region. The reason for this is that a fatigue crack at the toe can be found by in-service inspection while a fatigue crack starting at the root can not be discovered before the crack has grown through the weld. Thus the design of the weld geometry should be performed such that the fatigue life for cracks starting at the root is longer than the fatigue life of the toe. Figure 2-13 can be used for evaluation of required penetration. The notation used is explained by Figure 2-12.

It should be added that it is difficult to detect internal defects by NDE in fillet/partial penetration welds. Such connections should therefore not be used in structural connections of significant importance for the integrity.

2.9 Bolts

2.9.1 General

A bolted joint connection subjected to dynamic loading should be designed with pretensioned bolts. The pretension should be high enough to avoid slipping after relevant loss of pretension during service life.
2.9.2 Bolts subjected to tension loading
Connections where the pretensioned bolts are subjected to
dynamic axial forces should be designed with respect to
fatigue taking into account the stress range in the bolts result-
ing from tension and compression range. The stress range in
the bolts may be assessed based on e.g. “Maskindeler 2”, ref. /23/, or “Systematic Calculation of High Duty Bolted Joints”,
ref. /26/.

For S-N classification see Table A-2 of Appendix A.

2.9.3 Bolts subjected to shear loading
For bolts subject to shear loading the following methodology
may be used for fatigue assessment. The threads of the bolts
should not be in the shear plane. The methodology may be used
for fitted bolts or for normal bolts without load reversal. The
shear stress to be calculated based on the shank area of the bolt.
Then number of cycles to failure can be derived from

\[
\log N = 16.301 - 5.0 \log \Delta \sigma
\]

(2.9.1)

where \( \Delta \sigma \) = shear stress based on shaft area of bolt.

2.10 Pipelines and risers
2.10.1 Stresses at girth welds in pipes and S-N data
Welds in pipelines are normally made with a symmetric weld
groove with welding from the outside only. The tolerances are
rather strict compared with other structural elements with
eccentricity less than 0.1 \( t \) or maximum 3 \( mm \) (\( t = \) wall thick-
ness). The fabrication of pipelines also implies a systematic
and standardised NDE of the root area where defects are most
critical. Provided that the same acceptance criteria are used for
pipelines with larger wall thickness as for that used as refer-
ence thickness (25 \( mm \)), a thickness exponent \( k = 0 \) may be
used for hot spot at the root and \( k = 0.15 \) for the weld toe. Pro-
vided that these requirements are fulfilled, the detail at the root
side may be classified as F1 with SCF = 1.0, ref. Table 2-4. The
F-curve and SCF = 1.0 may be used for welding on temporary
backing, ref. Table 2-4.

Reference is made to Table 2-4 for other tolerances and weld-
ing from both sides.

For weld grooves that are not symmetrical in shape a stress
concentration for the weld root due to maximum allowable
eccentricity should be included. This stress concentration fac-
tor can be assessed based on the following analytical expres-
sion:

\[
SCF = 1 + \frac{3 \delta_m}{t} e^{-3 \sqrt{D/t}}
\]

(2.10.1)

where notations are shown in Figure 3-9.

This stress concentration factor can also be used for fatigue
assessments of the weld toes, ref. also Table 2-4.

The nominal stress on the outside of the pipe should be used
for fatigue assessment of the outside and the nominal stress on
the inside of the pipe should be used for fatigue assessment of
the inside. The membrane stress in the considered section
should be used for calculation of local bending stress over the
thickness together with stress concentration factor from equation (2.10.1).

Reference is also made to the commentary section.

2.10.2 Combined eccentricity for fatigue analysis of seam-
less pipes
For welded pipes it is ovality that normally will govern the
resulting eccentricity. Thus the effect of tolerances can simply
be added linearly.

For seamless pipes it is realised that the thickness tolerance
contributes by a similar magnitude to the resulting eccentricity.
A resulting tolerance to be used for calculation of stress con-
centration factor using equation (2.10.1) with \( \delta_m = \delta_{Tot} \) can
be obtained as:

\[
\delta_{Tot} = \sqrt{\delta_{Thickness}^2 + \delta_{Ovality}^2}
\]

(2.10.2)

where

\[
\delta_{Thickness} = (t_{max} - t_{min})/2
\]

\[
\delta_{Ovality} = (D_{max} - D_{min})/2 \text{ if the pipes are supported such that}
\]

flush outside at one point is achieved (no pipe
centralising)

\[
\delta_{Ovality} = (D_{max} - D_{min})/2 \text{ if the pipes are centralised dur-
}

ing construction}

\[
\delta_{Ovality} = (D_{max} - D_{min})/4 \text{ if the pipes are centralised dur-
}

ing construction and rotated until a good fit

around the circumference is achieved

Reference is made to DNV-OS-F101 Section 6 Clause E1200
for measurements of tolerances.

2.10.3 SCFs for pipes with internal pressure
Reference is made to commentary for stress concentration fac-
tors for other details in pipelines and cylindrical tanks with
stress cycling mainly due to internal pressure.
2.11 Guidance to when a detailed fatigue analysis can be omitted

A detailed fatigue analysis can be omitted if the largest local stress range for actual details defined in eq. (2.3.1) is less than the fatigue limit at 10^7 cycles in Table 2-1 for air and Table 2-2 for seawater with cathodic protection. For Design Fatigue Factors larger than 1 the allowable fatigue limit should also here be reduced by a factor (DFF)^-0.33. For definition of DFF see OS-C101 ref. /28/.

Requirements to detailed fatigue analysis may also be assessed based on the fatigue assessment charts in Figure 5-1 and Figure 5-2.

The use of the fatigue limit is illustrated in Figure 2-14. A detailed fatigue assessment can be omitted if the largest stress cycle is below the fatigue limit. However, in the example in Figure 2-15 there is one stress cycle Δσ₁ above the fatigue limit. This means that a further fatigue assessment is required. This also means that the fatigue damage from the stress cycles Δσ₂ has to be included in the fatigue assessment.

2.11 Guidance to when a detailed fatigue analysis can be omitted

A detailed fatigue analysis can be omitted if the largest local stress range for actual details defined in eq. (2.3.1) is less than the fatigue limit at 10^7 cycles in Table 2-1 for air and Table 2-2 for seawater with cathodic protection. For Design Fatigue Factors larger than 1 the allowable fatigue limit should also here be reduced by a factor (DFF)^-0.33. For definition of DFF see OS-C101 ref. /28/.

Requirements to detailed fatigue analysis may also be assessed based on the fatigue assessment charts in Figure 5-1 and Figure 5-2.

The use of the fatigue limit is illustrated in Figure 2-14. A detailed fatigue assessment can be omitted if the largest stress cycle is below the fatigue limit. However, in the example in Figure 2-15 there is one stress cycle Δσ₁ above the fatigue limit. This means that a further fatigue assessment is required. This also means that the fatigue damage from the stress cycles Δσ₂ has to be included in the fatigue assessment.

3. Stress Concentration Factors

3.1 Stress concentration factors for plated structures

3.1.1 General

A stress concentration factor may be defined as the ratio of hot spot stress range over nominal stress range.

3.1.2 Stress concentration factors for butt welds

The eccentricity between welded plates may be accounted for in the calculation of stress concentration factor. The following formula applies for a butt weld in an unstiffened plate or for a pipe butt weld with a large radius:

\[
SCF = 1 + \frac{3(\delta_m - \delta_a)}{t}
\]  

(3.1.1)

where

δ_m is eccentricity (misalignment) and t is plate thickness, see Figure 3-9.
δ₀ = 0.1 t is misalignment inherent in the S-N data for butt welds. See DNV-OS-C401 for fabrication tolerances.

The stress concentration for the weld between plates with different thickness in a stiffened plate field may be derived from the following formula:

\[
\text{SCF} = 1 + \frac{6(\delta_{m} + \delta_{t} - \delta_{b})}{t \left[ 1 + \frac{T^{1.5}}{t^{1.5}} \right]}
\]  

(3.1.2)

where

\( \delta_{m} \) = maximum misalignment
\( \delta_{t} = \frac{T}{2} - t \) eccentricity due to change in thickness.
Note: This applies also at transitions sloped as 1:4.
\( \delta_{0} = 0.1 t \) is misalignment inherent in the S-N data for butt welds. See DNV-OS-C401 for fabrication tolerances.

\( T \) = thickness of thicker plate
\( t \) = thickness of thinner plate

See also Figure 3-8.

3.1.3 Stress concentration factors for cruciform joints

The stress concentration factor for cruciform joint at plate thickness \( t_{i} \) may be derived from following formula:

\[
\text{SCF} = 1 + \frac{6t_{i}^{2}(\delta - \delta_{0})}{l_{i}\left( \frac{l_{1}^{2}}{l_{1}^{2}} + \frac{l_{2}^{2}}{l_{2}^{2}} + \frac{l_{3}^{2}}{l_{3}^{2}} + \frac{l_{4}^{2}}{l_{4}^{2}} \right)}
\]  

(3.1.3)

where

\( \delta = (\delta_{m} + \delta_{i}) \) is the total eccentricity
\( \delta_{0} = 0.3 t \) is misalignment embedded in S-N data for cruciform joints. See DNV-OS-C401 for fabrication tolerances.

\( t_{i} \) = thickness of the considered plate \( (i = 1, 2) \)
\( l_{i} \) = length of considered plate \( (i = 1, 2) \)

The other symbols are defined in Figure 3-1.

![Cruciform joint](image)

3.1.4 Stress concentration factors for rounded rectangular holes

Stress concentration factors for rounded rectangular holes are given in Figure 3-2.

Where there is one stress raiser close to another detail being evaluated with respect to fatigue, the interaction of stress between these should be considered. An example of this is a welded connection in a vicinity of a hole. Then the increase in stress at the considered detail due to the hole can be evaluated from Figure 3-3.

Some guidelines on effect of interaction of different holes can be found in Peterson’s “Stress Concentration Factors”, /15/).
3.1.5 Stress concentration factors for holes with edge reinforcement

Stress concentration factors for holes with reinforcement are given in Appendix C.

Fatigue cracking around a circumferential weld may occur at several locations at reinforced rings in plates depending on geometry of ring and weld size.

1) Fatigue cracking transverse to the weld toe in a region with a large stress concentration giving large stress parallel to the weld (Flexible reinforcement). See Figure 3-4a. Then \( \sigma_{\text{hot spot}} = \sigma_p \)

2) Fatigue cracking parallel to the weld toe (Stiff reinforcement).
ment with large weld size). See Figure 3-4b. Fatigue crack initiating from the weld toe. The principal stress $\sigma_1$ is the crack driving stress.

Then $\sigma_{\text{hot spot}} = \sigma_1$

Also the region at crown position to be checked.

Then $\sigma_{\text{hot spot}} = \sigma_n$

Alternatively to use the principal stress as hot spot stress at 45° position in Figure 3-4b one may use the concept of effective hot spot stress as described in section 4.3.4. Reference is also made to section 4.3.9.

3) Fatigue cracking from the weld root (Stiff reinforcement with small fillet weld size). See Figure 3-4c.

For fillet welds all these positions should be assessed with respect to fatigue. For full penetration welds the first two points should be assessed.

All these potential regions for fatigue cracking should be assessed in a design with use of appropriate stress concentration factors for holes with reinforcement.

For stresses to be used together with the different S-N curves see section 2.3.

**Potential fatigue cracking transverse to the weld toe**

For stresses parallel with the weld the local stress to be used together with the C curve is obtained with SCF from Appendix C ($\sigma_{\text{hot spot}}$ in Figure 3-4a).

**Potential fatigue cracking parallel with the weld toe**

For stresses normal to the weld the resulting hot spot stress to be used together with the D curve is obtained with SCF from Appendix C ($\sigma_{\text{hot spot}}$ in Figure 3-4b).

**Potential fatigue cracking from the weld root**

At some locations of the welds there are stresses in the plate transverse to the fillet weld, $\sigma_n$, and shear stress in the plate parallel with the weld $\tau_{//p}$ see Figure 3-4c. Then the fillet weld is designed for a combined stress obtained as

$$\Delta\sigma_w = \frac{t}{2a} \sqrt{\Delta\sigma_n^2 + 0.2\Delta \tau_{//p}^2} \quad (3.1.4)$$

where

$t$ = plate thickness

$a$ = throat thickness for a double sided fillet weld

The total stress range (i.e. maximum compression and maximum tension) should be considered to be transmitted through the welds for fatigue assessments. Reference is also made to Appendix C for an example.

Equation (3.1.4) can be outlined from equation (2.3.4) and the resulting stress range is to be used together with the W3 curve. The basic stress in the plate as shown in Figure 3-4 is derived from Appendix C.

3.1.6 Stress concentration factors for scallops

Reference is made to Figure 3-5 for stress concentration factors for scallops.

The stress concentration factors are applicable to stiffeners subject to axial loads. For significant dynamic pressure loads on the plate these details are susceptible to fatigue cracking and other design solutions should be considered to achieve a proper fatigue life.
3.2 Stress concentration factors for ship details
Stress concentration factors for ship details may be found in "Fatigue Assessment of Ship Structures" (CN 30.7), ref. [1]. S-N curve C from this Recommended Practice may be used if the procedure of CN 30.7 is used to determine the hot spot and $K_w$ stress. S-N curve D from this RP may be used if the procedure of CN 30.7 is used to determine the local stress (Excluding the notch stress concentration factor due to the weld geometry, $K_w$, from the analysis, as this factor is accounted for in the D-curve).

3.3 Tubular joints and members
3.3.1 Stress concentration factors for simple tubular joints
Stress concentration factors for simple tubular joints are given in Appendix B.

3.3.2 Superposition of stresses in tubular joints
The stresses are calculated at the crown and the saddle points, see Figure 3-6. Then the hot spot stress at these points is derived by summation of the single stress components from axial, in-plane and out-of-plane action. The hot spot stress may be higher for the intermediate points between the saddle and the crown. The hot spot stress at these points is derived by a linear interpolation of the stress due to the axial action at the crown and saddle and a sinusoidal variation of the bending stress resulting from in-plane and out of plane bending. Thus the hot spot stress should be evaluated at 8 spots around the circumference of the intersection, ref. Figure 3-7.

\[
\begin{align*}
\sigma_1 &= SCF_{AC} \sigma_x + SCF_{MOP} \sigma_{my} \\
\sigma_2 &= \frac{1}{2} (SCF_{AC} + SCF_{MOP}) \sigma_x + \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{my} - \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{mx} \\
\sigma_3 &= SCF_{AC} \sigma_x - SCF_{MOP} \sigma_{my} \\
\sigma_4 &= \frac{1}{2} (SCF_{AC} + SCF_{MOP}) \sigma_x - \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{my} - \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{mx} \\
\sigma_5 &= SCF_{AC} \sigma_x - SCF_{MOP} \sigma_{mx} \\
\sigma_6 &= \frac{1}{2} (SCF_{AC} + SCF_{MOP}) \sigma_x + \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{my} + \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{mx} \\
\sigma_7 &= SCF_{AC} \sigma_x + SCF_{MOP} \sigma_{my} \\
\sigma_8 &= \frac{1}{2} (SCF_{AC} + SCF_{MOP}) \sigma_x + \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{my} + \frac{1}{2} \sqrt{2} SCF_{MOP} \sigma_{mx} \\
\end{align*}
\]

(3.3.1)

Here $\sigma_x$, $\sigma_{my}$ and $\sigma_{mx}$ are the maximum nominal stresses due to axial load and bending in-plane and out-of-plane respectively. $SCF_{AS}$ is the stress concentration factor at the saddle for axial load and the $SCF_{AC}$ is the stress concentration factor at the crown. $SCF_{MIP}$ is the stress concentration factor for in plane moment and $SCF_{MOP}$ is the stress concentration factor for out of plane moment.
3.3.3 Tubular joints welded from one side

The root area of single-sided welded tubular joints may be more critical with respect to fatigue cracks than the outside region connecting the brace to the chord. In such cases, it is recommended that stubs are provided for tubular joints where high fatigue strength is required, such that welding from the backside can be performed.

Failure from the root has been observed at the saddle position of tubular joints where the brace diameter is equal the chord diameter, both in laboratory tests and in service. It is likely that fatigue cracking from the root might occur for rather low stress concentrations. Thus, special attention should be given to joints other than simple joints, such as ring-stiffened joints and joints where weld profiling or grinding on the surface is required to achieve sufficient fatigue life. It should be remembered that surface improvement does not increase the fatigue life at the root.

Based on experience it is not likely that fatigue cracking from the inside will occur earlier than from the outside for simple T and Y joints and K type tubular joints. The same consideration may be made for X-joints with diameter ratio $\beta \leq 0.90$. For other joints and for simple tubular X-joints with $\beta > 0.90$ it is recommended that a fatigue assessment of the root area is performed. Some guidance on such an assessment can be found in Appendix D, Commentary.

Due to limited accessibility for in service inspection a higher design fatigue factor should be used for the weld root than for the outside weld toe hot spot. Reference is also made to Appendix D, Commentary.

3.3.4 Stiffened tubular joints

Equations for joints for ring stiffened joints are given in “Stress Concentration Factors for Ring-Stiffened Tubular Joints”, ref. /3/. The following points should be noted regarding the equations:

- The derived SCF ratios for the brace/chord intersection and the SCF's for the ring edge are mean values, although the degree of scatter and proposed design factors are given.
- Short chord effects shall be taken into account where relevant.
- For joints with diameter ratio $\beta \geq 0.8$, the effect of stiffening is uncertain. It may even increase the SCF.
- The maximum of the saddle and crown stress concentration factor values should be applied around the whole brace/chord intersection.
- The following points can be made about the use of ring stiffeners in general:

Influence functions may be used as an alternative to the procedure given here to calculate hot spot stress. See e.g. “Combined Hot-Spot Stress Procedures for Tubular Joints”, ref. /24/ and “Development of SCF Formulae and Generalised Influence Functions for use in Fatigue Analysis” ref. /2/.
— Thin shell FE analysis should be avoided for calculating the SCF if the maximum stress is expected to be near the brace-ring crossing point in the fatigue analysis. An alternative is to use a three-dimensional solid element analysis model.
— Ring stiffeners have a marked effect on the circumferential stress in the chord, but have little or no effect on the longitudinal stress.
— Ring stiffeners outside the brace footprint have little effect on the SCF, but may be of help for the static strength.
— Failures in the ring inner edge or brace ring interface occur internally, and will probably only be detected after through thickness cracking, at which the majority of the fatigue life will have been expired. These areas should therefore be considered as non-inspectable unless more sophisticated inspection methods are used.

3.3.5 Grouted tubular joints

3.3.5.1 General
Grouted joints have either the chord completely filled with grout (single skin grouted joints) or the annulus between the chord and an inner member filled with grout (double skin grouted joints). The SCF of a grouted joint depends on load history and loading direction. The SCF is less if the bond between the chord and the grout is unbroken. For model testing of grouted joints the bond should be broken prior to SCF measurements. Due to the grout the tensile and compressive SCF may be different.

To achieve a fatigue design that is on the safe side it is recommended to use SCF's derived from tests where the bounds are broken and where the joint is subjected to tensile loading. The bounds can be broken by a significant tension load. This load may be determined during the testing by an evaluation of the force displacement relationship. (When incrementing the loading into a non-linear behaviour).

3.3.5.2 Chord filled with grout
The grouted joints shall be treated as simple joints, except that the chord thickness in the γ term for saddle SCF calculation for brace and chord shall be substituted with an equivalent chord wall thickness given by

\[ T_e = \frac{(5D + 134T)}{144} \]  
(3.3.2)

where D and T are chord diameter and thickness respectively. The dimensions are to be given in mm.

Joints with high β or low γ ratios have little effect of grouting. The benefits of grouting should be neglected for joints with β > 0.9 or γ ≤ 12.0 unless documented otherwise.

3.3.5.3 Annulus between tubular members filled with grout
For joints where the annulus between tubular members are filled with grout such as joints in legs with insert piles, the grouted joints shall be treated as simple joints, except that the chord thickness in SCF calculation for brace and chord shall be substituted with an equivalent chord wall thickness given by

\[ T_e = T + 0.457T_p \]  
(3.3.3)

where T is chord thickness and T_p is thickness of insert pile.

3.3.6 Cast nodes
It is recommended that finite element analysis should be used to determine the magnitude and location of the maximum stress range in castings sensitive to fatigue. The finite element model should use volume elements at the critical areas and properly model the shape of the joint. Consideration should be given to the inside of the castings. The brace to casting circumferential butt weld (which is designed to an appropriate S-N curve for such connections) may be the most critical location for fatigue.

3.3.7 Stress concentration factors for tubular butt weld connections
Due to less severe S-N curve for the outside weld toe than the inside weld root, it is strongly recommended that tubular butt weld connections subjected to axial loading are designed such that any thickness transitions are placed on the outside (see Figure 3-8). For this geometry, the SCF for the transition applies to the outside. On the inside it is then conservative to use SCF = 1.0. Thickness transitions are normally to be fabricated with slope 1:4.

Stress concentrations at tubular butt weld connections are due to eccentricities resulting from different sources. These may be classified as concentricity (difference in tubular diameters), differences in thickness of joined tubulars, out of roundness and centre eccentricity, see Figure 3-10 and Figure 3-11. The resulting eccentricity may be conservatively evaluated by a direct summation of the contribution from the different sources. The eccentricity due to out of roundness normally gives the largest contribution to the resulting eccentricity δ. It is conservative to use the formula for plate eccentricities for calculation of SCF at tubular butt welds. The effect of the diameter in relation to thickness may be included by use of the following formula, provided that T/t ≤ 2:

\[ SCF = 1 + \frac{6(\delta_e + \delta_m - \delta_a)}{t} e^{-\alpha} \]  
(3.3.4)

where

\[ \alpha = 1.82L \frac{1}{\sqrt{DT}} \frac{1}{1 + \left(\frac{T}{t}\right)^{0.8}} \]  
(3.3.5)

\[ \beta = 1.5 - \frac{1.0}{\log(D/t)} + \frac{3.0}{\log(D/t)^2} \]  
(3.3.6)

δ_m = 0.1 t is misalignment inherent in the S-N data

This formula also takes into account the length over which the eccentricity is distributed: L, ref. Figure 3-9 and Figure 3-8. The stress concentration is reduced as L is increased and or D is reduced. It is noted that for small L and large D the last formula provides stress concentration factors that are close to but lower than that of the simpler formula for plates.

The transition of the weld to base material on the outside of the tubular can normally be classified to S-N curve E. If welding is performed in a horizontal position it can be classified as D. This means that the pipe would have to be rotated during welding.

Equation (3.3.4) applies for the outside tubular side shown in Figure 3.8. For the inside the following formula may be used:

\[ SCF = 1 - \frac{6(\delta_e - \delta_m)}{t} e^{-\alpha} \]  
(3.3.7)

If the transition in thickness is on the inside of the tubular and the weld is made from both sides, equation (3.3.4) may be applied for the inside weld toe and equation (3.3.5) for the outside weld toe.

If the transition in thickness is on the inside of the tubular and the weld is made from the outside only, the following formulae
may be used for the inside weld root:

\[
SCF = 1 + \frac{6\delta t}{t} \frac{1}{1 + \left(\frac{T}{t}\right)^\beta} e^{-\alpha} \tag{3.3.6}
\]

And equation (3.3.5) may be applied for the outside weld toe.

**Figure 3-8**
Preferred transition in thickness is on outside of tubular butt weld

**Figure 3-9**
Section through weld

In tubulars, the root side of welds made from one side is normally classified as F3. This requires good workmanship during construction, in order to ensure full penetration welds, and that work is checked by non-destructive examination. It may be difficult to document a full penetration weld in most cases due to limitations in the non-destructive examination technique to detect defects in the root area. The F3 curve can be considered to account for some lack of penetration, but it should be noted that a major part of the fatigue life is associated with the initial crack growth while the defects are small. This may be evaluated by fracture mechanics such as described in BS 7910 “Guidance on Methods for Assessing the Acceptability of Flaws in Fusion Welded Structures”, ref /7/. Therefore, if a fabrication method is used where lack of penetration is to be expected, the design S-N curves should be adjusted to account for this by use of fracture mechanics.

For global moments over the tubular section it is the nominal stress derived at the outside that should be used together with an SCF from equation (3.3.4) for calculation of hot spot stress for fatigue assessment of the outside weld toe. The nominal stress on the inside should be used for assessment of fatigue cracks initiating from the inside.
3.3.8 Stress concentration factors for stiffened shells

The stress concentration at a ring stiffener can be calculated as

\[
SCF = \begin{cases} 
1 + \frac{0.54}{\alpha} & \text{for the outside of the shell} \\
1 - \frac{0.54}{\alpha} & \text{for the inside of the shell}
\end{cases}
\]

(3.3.7)

where

\[
\alpha = 1 + \frac{1.56t_r/rt}{A_r}
\]

Due to less stress on the inside it is more efficient to place ring stiffeners on the inside of shell, as compared with the outside. In addition, if the shell comprises longitudinal stiffeners that are ended, it is recommended to end the longitudinal stiffeners against ring stiffeners for the inside. The corresponding combination on the outside gives a considerably larger stress concentration.

The SCF = 1.0 if continuous longitudinal stiffeners are used. In the case of a bulkhead instead of a ring, \(A_r\) is taken as

\[
\frac{rt_b}{(1-v)}
\]

where \(t_b\) is the thickness of the bulkhead.

3.3.9 Stress concentration factors for conical transitions

The stress concentration at each side of unstiffened tubular-cone junction can be estimated by the following equations (the SCF shall be used together with the stress in the tubular at the junction for both the tubular and the cone side of the weld):

\[
SCF = 1 + \frac{0.6t_cD_j(t+t_c)}{t^2} \tan \alpha \quad \text{for the tubular side} \quad (3.3.8)
\]

\[
SCF = 1 + \frac{0.6t_cD_j(t+t_c)}{t_c^2} \tan \alpha \quad \text{for the cone side} \quad (3.3.9)
\]

where

\[
\begin{align*}
D_j &= \text{cylinder diameter at junction} \ (D_s, D_l) \\
t_c &= \text{tubular member wall thickness} \ (t_s, t_L) \\
t_c &= \text{cone thickness} \\
\alpha &= \text{the slope angle of the cone (see Figure 3-13)}
\end{align*}
\]
The stress concentration at a junction with ring stiffener can be calculated as

\[
SCF = 1 + \left(0.54 + \frac{0.91D_j t}{A_r} \tan \alpha \right) \frac{1}{\beta} \quad \text{at the outside smaller diameter junction}
\]

\[
SCF = 1 - \left(0.54 + \frac{0.91D_j t}{A_r} \tan \alpha \right) \frac{1}{\beta} \quad \text{at the inside smaller diameter junction}
\]

\[
SCF = 1 + \left(0.54 - \frac{0.91D_j t}{A_r} \tan \alpha \right) \frac{1}{\beta} \quad \text{(3.3.10)}
\]

at the outside larger diameter junction

\[
SCF = 1 - \left(0.54 - \frac{0.91D_j t}{A_r} \tan \alpha \right) \frac{1}{\beta} \quad \text{at the inside larger diameter junction, and}
\]

\[
\beta = 1 + \frac{1.10t \sqrt{D_j t}}{A_r}
\]

where

\[A_r = \text{area of ring stiffener without effective shell}\]

A ring stiffener may be placed centric at the cone junction. Then the butt weld should be ground and NDE examined before the ring stiffener is welded.

If a ring stiffener is placed a distance \( \delta_e \) away from the intersection lines, an additional stress concentration should be included to account for this eccentricity:

\[
SCF = 1 + \frac{3 \delta_e \tan \alpha}{t} \left(1 + \frac{I}{\sqrt{D_j^5 (t + t_r)^5}} \right) \quad \text{(3.3.11)}
\]

where

\[D_j = \text{cylinder diameter at junction (}\ D_s, \ D_L)\]

\[t = \text{tubular member wall thickness (}\ ts, \ t_L)\]

\[t_r = \text{cone thickness}\]

\[\alpha = \text{the slope angle of the cone (see Figure 3-13)}\]

\[I = \text{moment of inertia about the X-X axis in Figure 3-14 calculated as}\]

\[
l = b \frac{h^2}{12} + 0.5b (h + \frac{t_r}{2} - \bar{y})^2 (t_r + t_c) + t_c h (\frac{h^2}{12} + (\frac{h}{2} - \bar{y})^2)
\]

\[
\bar{y} = \frac{h^2 t_r + (h + \frac{t}{2}) b (t_r + t)}{2 h t_r + (t_r + t) b}
\]

where

\[h = \text{height of ring stiffener}\]

\[t_r = \text{thickness of ring stiffener}\]

\[b = \text{effective flange width calculated as}\]

\[
b = 0.78 \sqrt{D_j (t_r + t) + \delta_e}
\]

If a ring stiffener with a flange is used the effect of the flange should be included when calculating the moment of inertia about the neutral axis x-x shown in Figure 3-14.

The stress concentration factor from equation (3.3.11) shall be multiplied together with the relevant stress concentration factor from equation (3.3.10).

A full penetration weld connecting the ring stiffener to the tubular is often preferred as potential fatigue cracks from the root of fillet weld into the cylinder can hardly be detected during service inspection. If improvement methods are used for the weld toe the requirement of a full penetration weld will be enhanced.

Figure 3-13

Cone geometry
3.3.10 Stress concentration factors for tubulars subjected to axial force

This section applies to tubular sections welded together to long strings and subjected to axial tension. Tethers and risers of a TLP are examples of such structures.

The co-linearity with small angle deviation between consecutive fabricated tubular segments results in increased stress due to a resulting global bending moment, see Figure 3-16. The eccentricity due to co-linearity is a function of axial tension in the tubular and is significantly reduced as the axial force is increased by tension. Assuming that the moment $M$ results from an eccentricity $\delta_N$ where pretension is accounted for in the analysis, the following derivation of a stress concentration factor is performed:

$$\sigma = \frac{N}{\pi(D - t)t} \text{SCF}$$  \hspace{1cm} (3.3.15)

where the stress concentration factor is:

$$\text{SCF} = 1 + \frac{4\delta_N}{D - t}$$  \hspace{1cm} (3.3.16)

where $\delta_N$ is eccentricity as function of the axial force $N$ and $D$ is outer diameter. The eccentricity for two elements is indicated in Figure 3-16. With zero tension the eccentricity is $\delta$. With an axial tension force $N$ the eccentricity becomes:

$$\delta_N = \delta \frac{\tanh kl}{kl}$$  \hspace{1cm} (3.3.17)

where

$$k = \sqrt{\frac{N}{Et}}$$

$I$ = segment lengths of the tubulars

$N$ = axial force in tubulars

$I$ = moment of inertia of tubulars

$E$ = Young’s modulus

The formula for reduction in eccentricity due to increased axial force can be deduced from differential equation for the deflected shape of the model shown in Figure 3-16. Thus the non-linearity in terms of geometry is included in the formula for the stress concentration factor.

Judgement should be used to evaluate the number of elements to be considered, and whether deviation from a straight line is systematic or random, ref. Figure 3-15. In the first case, the errors must be added linearly, in the second case it may be added quadratically.

3.3.11 Stress concentration factors for joints with square sections

Stress concentration factors must be determined for the particular geometries being used in a design. These may be established from finite element analysis or from parametric equations where these can be found for the joints under consideration.

Stress concentration factors for square to square joints may be found in "Design guide for circular and rectangular hollow section welded joints under fatigue loading", ref. /27/. These stress concentration factors may be used together with the D-curve.

The following stress concentration factors may be used for $d/ D_w = 1.0$, where $d$ = depth and width of brace; $D_w$ = depth and width of chord:

- Axial: 1.90
- In-plane bending: 4.00
- Out-of plane bending: 1.35

These stress concentration factors should be used together with the F-curve.
3.3.12 Stress concentration factors for joints with gusset plates

Insert gusset plates are sometimes used in joints in topside structures to connect RHS and tubular members. Reference is made to Figure 3-17. When such connections are subjected to dynamic loading a full penetration weld between the member and the gusset plate is preferred. Otherwise it is considered difficult to document the fatigue capacity for fatigue cracking starting from the weld root. In dynamic loaded structures it is difficult to account for the S-N curve, as some of the local stress due to a detail is accounted for in the S-N curve.

Where a reliable fatigue life is to be documented it is recommended to perform finite element analysis if the geometry is significantly different from that shown in Figure 3-17b. The stress concentration factors in Table 3-1 are derived from finite element analysis using shell elements. Then the hot spot stress can be combined with the D-Curve. The stress concentration factor for tubular member is simply derived by scaling the results from that of RHS by $\pi/4$ for the same thickness. Using shell elements for such analysis provides conservative stress concentration factors as compared with use of three-dimensional elements with modelling also of the fillet weld. (It is here assumed that a fillet weld also can be used on the outside on a full or partial penetration weld). In a relevant example the resulting SCF using a model with three-dimensional elements was only 0.70 of that from analysis using a shell model. Thus the SCFs in Table 3-1 might be further reduced if necessary.

4. Calculation of hot spot stress by finite element analysis

4.1 General

From detailed finite element analysis of structures it may be difficult to evaluate what is “nominal stress” to be used together with the S-N curves, as some of the local stress due to a detail is accounted for in the S-N curve.

In many cases it may therefore be more convenient to use an alternative approach for calculation of fatigue damage when local stresses are obtained from finite element analysis. It is realised that it is difficult to calculate the notch stress at a weld due to a significant scatter in local weld geometry and different types of imperfections. This scatter is normally more efficiently accounted for by use of an appropriate S-N curve. In this respect it should also be mentioned that the weld toe region has to be modelled with a radius in order to obtain reliable results for the notch stress.

If a corner detail with zero radius is modelled the calculated stress will approach infinity as the element size is decreased to zero. The modelling of a relevant radius requires a very fine element mesh, increasing the size of the computer model. The notch stress concept may be used in special cases where other methods are not found appropriate, see Appendix D, Commentary.

Hence, for design analysis a simplified numerical procedure is used in order to reduce the demand for large fine mesh models for the calculation of SCF factors:

- The stress concentration or the notch factor due to the weld itself is included in the S-N curve to be used, the D-curve.
- The stress concentration due to the geometry effect of the actual detail is calculated by means of a fine mesh model using shell elements (or solid elements), resulting in a geometric SCF factor.

This procedure is denoted the hot spot method.

It is important to have a continuous and not too steep, change in the density of the element mesh in the areas where the hot spot stresses are to be analysed.

The geometry of the elements should be evaluated carefully in order to avoid errors due to deformed elements (for example corner angles between 60° and 120° and length/breadth ratio less than 5 are recommended).

The size of the model should be so large that the calculated results are not significantly affected by assumptions made for boundary conditions and application of loads.

It should be noted that the hot spot concept cannot be used for fatigue checks of cracks starting from the weld root of fillet/partial penetration welds. A fillet weld should be checked separately considering the stresses in the weld itself, ref. section 2.3.5.

4.2 Tubular joints

The stress range at the hot spot of tubular joints should be combined with the T-curve.

Analysis based on thick shell elements may be used. In this case, the weld is not included in the model. The hot spot stress may be determined as for welded connections.

More reliable results are obtained by including the weld in the model. This implies use of three-dimensional elements. Here the Gaussian points, where stresses are calculated, may be placed $0.1\sqrt{r_f}$ from the weld toe ($r = \text{radius of considered tubular}$ and $t = \text{thickness}$). The stress at this point may be used directly in the fatigue assessment.
4.3 Welded connections other than tubular joints

4.3.1 Stress field at a welded detail

Due to the nature of the stress field at a hot spot region there are questions on how to establish the hot spot stress, see Figure 4-1. The notch effect due to the weld is included in the S-N curve and the hot spot stress is derived by extrapolation of the structural stress to the weld toe as indicated in Figure 4-1. It is observed that the stress used as basis for such an extrapolation should be outside that affected by the weld notch, but close enough to pick up the hot spot stress.

4.3.2 FE modelling

The following guidance is made to the computation of hot spot stresses with potential fatigue cracking from the weld toe with local models using the finite element method.

Hot spot stresses are calculated assuming linear material behaviour and using an idealized structural model with no fabrication-related misalignment. The extent of the local model has to be chosen such that effects due to the boundaries on the structural detail considered are sufficiently small and reasonable boundary conditions can be formulated.

In plate structures, three types of hot spots at weld toes can be identified as exemplified in Figure 4-3:

a) at the weld toe on the plate surface at an ending attachment
b) at the weld toe around the plate edge of an ending attachment
c) along the weld of an attached plate (weld toes on both the plate and attachment surface).

Models with thin plate or shell elements or alternatively with solid elements are normally used. It should be noted that on the one hand the arrangement and type of elements have to allow for steep stress gradients as well as for the formation of plate bending, and on the other hand, only the linear stress distribution in the plate thickness direction needs to be evaluated with respect to the definition of hot spot stress.

The following methods of modelling are recommended.

The simplest way of modelling is offered by thin plate and shell elements which have to be arranged in the mid-plane of the structural components, see also Figure 4-4.

8-noded elements are recommended particularly in case of steep stress gradients. Care should be given to possible stress underestimation especially at weld toes of type b) in Figure 4-3. Use of 4-noded elements with improved in-plane bending modes is a good alternative.

The welds are usually not modelled except for special cases where the results are affected by high local bending, e.g. due to an offset between plates or due to a small free plate length between adjacent welds such as at lug (or collar) plates. Here, the weld may be included by transverse plate elements having appropriate stiffness or by introducing constrained equations for coupled node displacements.

A thickness equal 2 times the thickness of the plates may be used for modelling of the welds by transverse plates.

For 4-node shell elements with additional internal degrees of freedom for improved in plane behaviour and for 8-node shell elements a mesh size from t x t up to 2 t x 2 t may be used. Larger mesh sizes at the hot spot region may provide non-conservative results. (For efficient read out of element stresses and hot spot stress derivation a mesh txt is in general preferred at the hot spot region).

An alternative particularly for complex cases is offered by solid elements which need to have a displacement function allowing steep stress gradients as well as plate bending with linear stress distribution in the plate thickness direction. This is offered, e.g., by isoparametric 20-node elements (with mid-side nodes at the edges) which mean that only one element in plate thickness direction is required. An easy evaluation of the membrane and bending stress components is then possible if a reduced integration order with only two integration points in the thickness direction is chosen. A finer mesh sub-division is necessary particularly if 8-noded solid elements are selected. Here, at least four elements are recommended in thickness direction. Modelling of the welds is generally recommended and easily possible as shown in Figure 4-5.

For modelling with three dimensional elements the dimensions of the first two or three elements in front of the weld toe should be chosen as follows. The element length may be selected to correspond to the plate thickness. In the transverse direction, the plate thickness may be chosen again for the breadth of the plate elements. However, the breadth should not exceed the "attachment width", i.e. the thickness of the attached plate plus 2 x the weld leg length (in case of type c: the thickness of the web plate behind plus 2 x weld leg length). The length of the elements should be limited to 2 t.

In cases where three-dimensional elements are used for the FE modelling it is recommended that also the fillet weld is modelled to achieve proper local stiffness and geometry.

In order to capture the properties of bulb sections with respect to St Venant torsion it is recommended to use several three-dimensional elements for modelling of a bulb section. If in addition the weld from stiffeners in the transverse frames is modelled the requirements with respect to element shape will likely govern the FE model at the hot spot region.

4.3.3 Derivation of stress at read out points 0.5 t and 1.5 t

The stress components on the plate surface should be evaluated along the paths shown in Figure 4-4 and Figure 4-5 and extrapolated to the hot spot. The average stress components between adjacent elements are used for the extrapolation.

Recommended stress evaluation points are located at distances 0.5 t and 1.5 t away from the hot spot, where t is the plate thickness at the weld toe. These locations are also denoted as stress read out points.

If the element size at a hot spot region of size txt is used, the stresses may be evaluated as follows:

- In case of plate or shell elements the surface stress may be evaluated at the corresponding mid-side points. Thus the stresses at mid side nodes along line A-B in Figure 4-2 may be used directly as stress at read out points 0.5 t and 1.5 t.

- In case of solid elements the stress may first be extrapolated from the Gaussian points to the surface. Then these stresses can be interpolated linearly to the surface centre or extrapolated to the edge of the elements if this is the line for hot spot stress derivation.

For meshes with 4-node shell elements larger than t x t it is recommended to fit a second order polynomial to the element stresses in the three first elements and derive stresses for extrapolation from the 0.5 t and 1.5 t points. An example of this is shown schematically in Figure 4-6. This procedure may be used to establish stress values at the 0.5 t and 1.5 t points. For 8-node elements a second order polynomial may be fitted to the stress results at the mid-side nodes of the three first elements and the stress at the read out points 0.5 t and 1.5 t can be derived.

4.3.4 Derivation of hot spot stress

Two alternative methods can be used for hot spot stress derivation: method A and method B.

Method A

For modelling with shell elements without any weld included in the model a linear extrapolation of the stresses to the intersection line from the read out points at 0.5t and 1.5t from the
interconnection line can be performed to derive hot spot stress.

For modelling with three-dimensional elements with the weld included in the model a linear extrapolation of the stresses to the weld toe from the read out points at 0.5t and 1.5t from the weld toe can be performed to derive hot spot stress.

The notations for stress components are shown in Figures 2-3 and 2-4.

The effective hot spot stress range to be used together with the hot spot S-N curve is derived as

\[
\Delta \sigma_{\text{eff}} = \max \left( \alpha \left| \Delta \sigma_1 \right|, \alpha \left| \Delta \sigma_2 \right| \right) 
\]

where

\[
\alpha = \begin{cases} 0.90 & \text{if the detail is classified as C2 with stress parallel to the weld at the hot spot, ref. Table A-3.} \\ 0.80 & \text{if the detail is classified as C1 with stress parallel to the weld at the hot spot, ref. Table A-3.} \\ 0.72 & \text{if the detail is classified as C with stress parallel to the weld at the hot spot, ref. Table A-3.} 
\end{cases}
\]

The first principal stress is calculated as

\[
\Delta \sigma_1 = \frac{\Delta \sigma_{11} + \Delta \sigma_{22}}{2} + \frac{1}{2} \sqrt{\left( \Delta \sigma_{11} - \Delta \sigma_{22} \right)^2 + 4 \Delta \tau_{12}^2} 
\]

and

\[
\Delta \sigma_2 = \frac{\Delta \sigma_{11} + \Delta \sigma_{22}}{2} - \frac{1}{2} \sqrt{\left( \Delta \sigma_{11} - \Delta \sigma_{22} \right)^2 + 4 \Delta \tau_{12}^2} 
\]

The equation for effective stress is made to account for the situation with fatigue cracking along a weld toe as shown in Figure 2-3 and fatigue cracking when the principal stress direction is more parallel with the weld toe as shown in Figure 2-4.

**Method B**

For modelling with shell elements without any weld included in the model the hot spot stress is taken as the stress at the read out point 0.5t away from the intersection line.

For modelling with three-dimensional elements with the weld included in the model the hot spot stress is taken as the stress at the read out point 0.5t away from the weld toe.

The effective hot spot stress range is derived as

\[
\Delta \sigma_{\text{eff}} = \max \left( 1.12 \sqrt{\Delta \sigma_1^2 + 0.81 \Delta \tau_1^2}, 1.12 \alpha \left| \Delta \sigma_2 \right| \right) 
\]

where

\[
\alpha, \Delta \sigma_1 \text{ and } \Delta \sigma_2 \text{ are explained under method A.}
\]

The equation for effective stress is made to account for the situation with fatigue cracking along a weld toe as shown in Figure 2-3 and fatigue cracking when the principal stress direction is more parallel with the weld toe as shown in Figure 2-4.

**4.3.5 Hot spot S-N curve**

It is recommended to link the derived hot spot stress to the D-curve.

**4.3.6 Derivation of effective hot spot stress from FE analysis**

At hot spots with significant plate bending one might derive an effective hot spot stress for fatigue assessment based on the following equation:

\[
\Delta \sigma_{\text{eff,hot spot}} = \Delta \sigma_{\text{hot spot}} + 0.60 \Delta \sigma_{\text{b,hot spot}} 
\]

**4.3.7 Limitations for simple connections**

It should be noted that the definition of the stress field through the plate thickness in section 4.3.1 implies that the described hot spot stress methodology is not recommended for simple cruciform joints, simple T-joints in plated structures or simple butt joints that are welded from one side only. Analyzing such connections with for example shell elements would result in a hot spot stress equal the nominal stress. This is illustrated by the shell model shown in Figure 4-7. For stresses in the direction normal to the shell (direction I) there will be no stress flow into the transverse shell plating as it is represented only by one plane in the shell model. However, it attracts stresses for in-plane (direction II) shown in Figure 4-7.

As the nominal stress S-N curve for direction I is lower than that of the D-curve, it would be non-conservative to use the hot spot concept for this connection for direction I while it would be acceptable for direction II at position “a”. Thus, the nominal stress approach is recommended used for direction I at position “c” as also the nominal stress can be easily derived for analysis of these connections.

It should also be noted that it is for these joints (butt welds and cruciform joints) that fabrication tolerances are most important and need to be considered in a fatigue assessment.

The described hot spot concept linked to the D-curve is giving acceptable results as soon as there is a bracket behind the transverse plate as shown in Figure 4-3 acting with its stiffness in the direction of I (Figure 4-7).

The reader should also be made aware of another case that is linked to the same problem. When analysing a brace with a simple ring stiffener the hot spot stress will include the effect of decreased stress on the inside and increased stress on the outside due to the circumferential stiffness of the ring. However, the ring will not attract stress normal to its plane. Therefore, a lower S-N curve than D has to be used; see Tables of S-N classification. From a finite element analysis using shell elements the largest stress at the node at the ring stiffener should be used as nominal stress. This is important at an outside ring stiffener in order to include the bending stress in the shell due to its deformed shape, ref. Figure 3.3. Ref. also fatigue analysis of the drum in Appendix D, Commentary.

In a case that a longitudinal stiffener is ended at a circumferential ring stiffener the described procedure using S-N curve D will again be working.
4.3.8 Verification of analysis methodology

The analysis methodology may be verified based on analysis of details with derived target hot spot stress. Such details with target hot spot stress are shown in Appendix D, Commentary.

4.3.9 Analysis of welded penetrations

Finite element analysis is normally used to analyse plated structures in floating offshore structures. The welded penetrations are normally not included in the analysis models due to modelling time and analysis capacity. At a position of a penetration a two-dimensional stress field is calculated using shell elements for modelling of the plated structures. This implies stresses in x- and y-direction in the coordinate system of the element and a shear stress. From these stresses the principal stresses can be calculated as

\[
\Delta \sigma_1 = \frac{\Delta \sigma_x + \Delta \sigma_y}{2} + \frac{1}{2} \sqrt{(\Delta \sigma_x - \Delta \sigma_y)^2 + 4 \Delta \tau_{xy}^2} \\
\Delta \sigma_2 = \frac{\Delta \sigma_x + \Delta \sigma_y}{2} - \frac{1}{2} \sqrt{(\Delta \sigma_x - \Delta \sigma_y)^2 + 4 \Delta \tau_{xy}^2}
\]  

(4.3.6)

Stresses for fatigue design at position a) in Figure 4-8

For a single stress state the hot spot stress at position a in Figure 4-8 can be derived from the graphs in Figures C-3 and C-4 in Appendix C for hot spot position shown in left part of Figure 4-9. These graphs can be used to calculate the stress range due to the first principal stress.

This principal stress will also create a parallel stress at position c as shown in Figure 4-9. The graph in Figure C-15 can be used to calculate the hot spot stress at position a (Figure 4-8) for the second principal stress (shown to the right in Figure 4-9).

Then the resulting hot spot stress due to the first and the second principal stresses are derived by summation of derived hot spot stresses. Finally this hot spot stress can be entered into the curve C for calculation of fatigue damage.

Stresses for fatigue design at position b) in Figure 4-8

The stress components normal to and parallel with the weld toe (see Figure 3.4 for notations) are evaluated for first principal stress and for the second principal stress shown in Figure 4-8 separately. Then these stress components are added together before they are inserted into equations (4.3.7) and (4.3.8).
Then the principal stresses at position b in Figure 4-8 can be calculated as
\[
\Delta \sigma_{ib} = \frac{\Delta \sigma_{u} + \Delta \sigma_{\text{ip}}}{2} + \frac{1}{2} \sqrt{\left( \Delta \sigma_{u} - \Delta \sigma_{\text{ip}} \right)^2 + 4 \Delta \tau_{\text{ip}}^2}
\]
\[
\Delta \sigma_{2b} = \frac{\Delta \sigma_{u} + \Delta \sigma_{\text{ip}}}{2} - \frac{1}{2} \sqrt{\left( \Delta \sigma_{u} - \Delta \sigma_{\text{ip}} \right)^2 + 4 \Delta \tau_{\text{ip}}^2}
\]
(4.3.7)

Finally the effective hot spot stress at position b is calculated as
\[
\Delta \sigma_{eb} = \max \left( 0.72 \Delta \sigma_{ib}, 0.72 \Delta \sigma_{2b} \right)
\]
(4.3.8)

Then this stress range is entered the hot spot stress curve D.

**Stresses for fatigue design at position c** in Figure 4-8

Graphs for stress concentration factors for the conditions shown in Figure 4-10 are required for calculation of hot spot stress at position c in figure 4-8. One set of stress concentration factors is combined with the first principal stress and another set of stress concentration factors is combined with the second principal stress, see graphs in Appendix C. Then these hot spot stresses are added together before the D-curve is entered for calculation of fatigue damage.

To be analysed with $\Delta \sigma_1$

To be analysed with $\Delta \sigma_2$

Figure 4-10

Stresses required for derivation of hot spot stress at position c in Figure 4-8

### 5. Simplified fatigue analysis

#### 5.1 General

The long term stress range distribution may be presented as a two-parameter Weibull distribution

\[
Q(\Delta \sigma) = \exp \left[ - \left( \frac{\Delta \sigma}{\text{h}} \right)^\text{q} \right]
\]
(5.1.1)

where

- $Q$ = probability for exceedance of the stress range $\Delta \sigma$
- $h$ = Weibull shape parameter
- $q$ = Weibull scale parameter is defined from the stress range level, $\Delta \sigma_0$, as:

\[
q = \frac{\Delta \sigma_0}{(\ln n_0)^{1/h}} \quad (5.1.2)
\]

$\Delta \sigma_0$ is the largest stress range out of $n_0$ cycles.

When the long-term stress range distribution is defined applying Weibull distributions for the different load conditions, and a one-slope S-N curve is used, the fatigue damage is given by

\[
D = \frac{\nu T_d}{\bar{h}} q^n \Gamma(1 + \frac{m}{h}) \leq \eta
\]
(5.1.3)

where

- $T_d$ = design life in seconds
- $h$ = Weibull stress range shape distribution parameter
- $q$ = Weibull stress range scale distribution parameter
- $\nu_0$ = average zero-crossing frequency
- $\Gamma(1 + \frac{m}{h})$ = gamma function. Values of the gamma function are listed in Table 5-1.

Use of one slope S-N curves leads to results on the safe side for calculated fatigue lives (with slope of curve at $N < 10^6 - 10^7$ cycles).

For other expressions for fatigue damage see Appendix D, Commentary.

#### 5.2 Fatigue design charts

Design charts for steel components in air and in seawater with cathodic protection are shown in Figure 5-1 and Figure 5-2 respectively. These charts have been derived based on the two slopes S-N curves given in this RP. The corresponding numerical values are given in Table 5-2 and Table 5-3.

These design charts have been derived based on an assumption of an allowable fatigue damage $\eta = 1.0$ during $10^8$ cycles (20 years service life which corresponds to an average period of 6.3 sec). For design with other allowable fatigue damages, $\eta$, the allowable stress from the design charts should be reduced by factors derived from Table 5-4 and Table 5-5 for conditions in air and Table 5-6 and Table 5-7 for conditions in seawater with cathodic protection.

The fatigue utilisation factor $\eta$ as a function of design life and design fatigue factor (DFF) is given in Table 5-8.

The stresses derived here correspond to the reference thickness. For thickness larger than the reference thickness, an allowable extreme stress range during $10^8$ cycles may be
obtained as

\[ \sigma_{0,t} = \sigma_{0,\text{ref}} \left( \frac{t_{\text{ref}}}{t} \right)^k \]  

(5.2.1)

where

- \( k \) = thickness exponent, see section 2.4 and Table 2-1, Table 2-2 and Table 2-3
- \( \sigma_{0,\text{ref}} \) = allowable stress as derived from Table 5-2 and Table 5-3

5.3 Example of use of design charts

The allowable stress range in the deck structure of a FPSO is to be determined.

The maximum thickness of the steel plates is 35.0 mm. From DNV Classification Note No. 30.7 a Weibull shape parameter equal 0.97 is determined. It is assumed that details with a classification F3 is going to be welded to the deck structure.

The design life of the FPSO is 25 years and the operator would like to use a Design Fatigue Factor equal 2.

The detail is in air environment. Then by a linear interpolation of stress ranges for h-values 0.90 and 1.0 in Table 5-2 for S-N curve F3 is obtained:

\[ 199.6 - (199.6 - 169.0) \frac{(0.97 - 0.90)}{(1.0 - 0.90)} = 178.18 \text{ MPa}. \]

This corresponds to an allowable stress for 20 years design life and a DFF equal 1. Then from Table 5-8 an utilisation factor \( \eta = 0.40 \) is obtained for 25 years service life and a DFF equal 2.0.

Then from Table 5-5 a reduction factor is obtained by linear interpolation between the factors for h-values 0.90 and 1.0 for \( \eta = 0.40 \). The following reduction factor is obtained:

---

A linear elastic finite element analysis approach combined with S-N curve B1 without requirement to additional fatigue testing

2) Advanced finite element analysis approach with non-linear analysis to determine initial behaviour before an elastic state is achieved. Then the stress range may be combined with the high strength S-N curve. These analyses may be supported by additional fatigue testing depending on consequences of a fatigue failure.

For assessment of a fatigue design curve for connectors derived from testing as described in Appendix D section D.7, the stress modification parameter (SMF) accounts for a number of different parameters:

- Stress concentration factor in connection.
- Stress gradient at threads.
- Fabrication tolerances in connecting parts.
- Make-up torque.
- Local yielding at thread roots.
- Mean stress effects when the testing is performed with part of the stress cycle as compressive. Ref. section 2.5.

The uncertainty in these parameters should be assessed when determining standard deviation to be used in derivation of a design S-N curve based on few new test data.

It is assumed that connectors are subjected to 100% NDT and that surface defects are not allowed such that a homogenous data set would be expected if many connectors were fatigue tested.

If the calculated stress concentration in a connector is depend-ent on load level and load sequence, it is recommend to put on a load that the connector will likely experience during the first year of service, to allow for local yielding at high stressed areas, before a load range typically corresponding to the region with highest contribution to fatigue damage is selected for analysis of stress concentration factor based on linear elastic analysis. Similar considerations may also be made for fatigue testing of these connections.

6. Fatigue analysis based on fracture mechanics

Fracture mechanics may be used for fatigue analyses as supplement to S-N data.

Fracture mechanics is recommended for use in assessment of acceptable defects, evaluation of acceptance criteria for fabrication and for planning in-service inspection.

The purpose of such analysis is to document, by means of calculations, that fatigue cracks, which might occur during service life, will not exceed the crack size corresponding to unstable fracture. The calculations should be performed such that the structural reliability by use of fracture mechanics will not be less than that achieved by use of S-N data. This can be achieved by performing the analysis according to the following procedure:

- crack growth parameter C determined as mean plus 2 standard deviation
- a careful evaluation of initial defects that might be present in the structure when taking into account the actual NDE inspection method used to detect cracks during fabrication
- use of geometry functions that are on the safe side
- use of utilisation factors similar to those used when the fatigue analysis is based on S-N data.

As crack initiation is not included in the fracture mechanics approach, shorter fatigue life is normally derived from fracture mechanics than by S-N data.

In a case that the results from fracture mechanics analyses cannot directly be compared with S-N data it might be recommended to perform a comparison for a detail where S-N data are available, in order to verify the assumptions made for the fracture mechanics analyses.

The initial crack size to be used in the calculation should be considered in each case, taking account of experienced imperfection or defect sizes for various weldments, geometries, access and reliability of the inspection method. For surface cracks starting from transitions between weld/base material, a crack depth of 0.5 mm (e.g. due to undercuts and microcracks at bottom of the undercuts) may be assumed if other documented information about crack depth is not available.

It is normally, assumed that compressive stresses do not contribute to crack propagation. However, for welded connections containing residual stresses, the whole stress range should be applied. Only stress components normal to the propagation plane need to be considered.

The Paris’ equation may be used to predict the crack propagation or the fatigue life:

\[
\frac{da}{dN} = C(\Delta K)^m
\]

where

\[
\Delta K = K_{\text{max}} - K_{\text{min}}
\]

\[
N = \text{Number of cycles to failure}
\]

\[
a = \text{crack depth. It is here assumed that the crack depth/length ratio is low (less than 1:5)}
\]
where
\[ \sigma \] = nominal stress in the member normal to the crack
\[ g \] = factor depending on the geometry of the member and the crack

See BS 7910, ref. /7/, for further guidelines related to fatigue assessment based on fracture mechanics.

7. Improvement of Fatigue Life by Fabrication

7.1 General

It should be noted that improvement of the toe will not improve the fatigue life if fatigue cracking from the root is the most likely failure mode. The considerations made in the following are for conditions where the root is not considered to be a critical initiation point. Except for weld profiling (section 7.2) the effect from different improvement methods as given in the following can not be added.

Reference is made to IIW Recommendations, on post weld improvement with respect to execution of the improvement.

7.2 Weld profiling by machining and grinding

By weld profiling in this section is understood profiling by machining or grinding as profiling by welding only is not considered to be an efficient mean to improve fatigue lives.

In design calculations, the thickness effect may be reduced to an exponent 0.15 provided that the weld is profiled by either machining or grinding to a radius of approximately half the plate thickness, \((T/2)\) with stress direction as shown in Figure 7-2 B.

Where weld profiling is used, the fatigue life can be increased taking account of a reduced local stress concentration factor. A reduced local stress due to weld profiling can be obtained as follows.

When weld profiling is performed, a reduced hot spot stress can be calculated as

\[ \sigma_{\text{Local reduced}} = \sigma_{\text{Membrane}} \alpha + \sigma_{\text{Bending}} \beta \] (7.2.1)

where \( \alpha \) and \( \beta \) are derived from equations (7.2.2) and (7.2.3) respectively.

\[ \alpha = 0.47 + 0.17(\tan \alpha)^{0.25}(T/R)^{0.5} \] (7.2.2)

\[ \beta = 0.60 + 0.13(\tan \alpha)^{0.25}(T/R)^{0.5} \] (7.2.3)

For description of geometric parameters see Figure 7-1.

The membrane part and the bending part of the stress have to be separated from the local stress as

\[ \sigma_{\text{Local}} = \sigma_{\text{Membrane}} + \sigma_{\text{Bending}} \] (7.2.4)

where

\( \sigma_{\text{Membrane}} \) = membrane stress
\( \sigma_{\text{Bending}} \) = bending stress

If a finite element analysis of the considered connection has been performed, the results from this can be used directly to derive membrane stress and bending stress.

For cruciform joints and heavy stiffened tubular joints it may be assumed that the hot spot stress is mainly due to membrane stress.

For simple tubular joints it may be assumed that the hot spot stress in the chord is due to bending only.

The reduced local stress in equation (7.2.1) is to be used together with the same S-N curves as the detail is classified for without weld profiling. (It is assumed that \( R/T = 0.1 \) without weld profiling for a plate thickness \( T = 25 \text{mm} \)).

In addition the fatigue life can be increased taking account of local toe grinding, reference is made to Section 7.3. However, the maximum improvement factor from grinding only should then be limited to a factor 2 on fatigue life.

7.3 Weld toe grinding

Where local grinding of the weld toes below any visible undercuts is performed the fatigue life may be increased by a factor given in Table 7-1. In addition the thickness effect may be reduced to an exponent \( k = 0.20 \). Reference is made to Figure 7-2. Grinding a weld toe tangentially to the plate surface, as at A, will produce only little improvement in fatigue strength. To be efficient, grinding should extend below the plate surface, as at B, in order to remove toe defects. Grinding is normally carried out by a rotary burr. The treatment should produce a smooth concave profile at the weld toe with the depth of the depression penetrating into the plate surface to at least 0.5 mm below the bottom of any visible undercut (see Figure 7-2). The grinding depth should not exceed 2 mm or 7% of the plate thickness, whichever is smaller.

In general grinding has been used as an efficient method for reliable fatigue life improvement after fabrication. Grinding also improves the reliability of inspection after fabrication and during service life. However, experience indicates that it may be a good design practice to exclude this factor at the design stage. The designer is advised to improve the details locally by other means, or to reduce the stress range through design and keep the possibility of fatigue life improvement as a reserve to allow for possible increase in fatigue loading during the design and fabrication process, see also DNV-OS-C101 Design of Steel Structures, section 6.

It should also be noted that if grinding is required to achieve a specified fatigue life, the hot spot stress is rather high. Due to grinding a larger fraction of the fatigue life is spent during the initiation of fatigue cracks, and the crack grows faster after initiation. This implies use of shorter inspection intervals during service life in order to detect the cracks before they become.
dangerous for the integrity of the structure.
For grinding of weld toes it is recommended to use a rotary ball shaped burr with typical diameter of 12 mm.

However, the following limitations apply:
— Hammer peening should only be used on members where failure will be without substantial consequences, ref. OS-C101 Design of Steel Structures, Section 6.
— Overload in compression must be avoided, because the residual stress set up by hammer peening will be destroyed.
— It is recommended to grind a steering groove by means of a rotary burr of a diameter suitable for the hammer head to be used for the peening. The peening tip must be small enough to reach weld toe.

Due to uncertainties regarding workmanship and quality assurance of the process, this method may not be recommendable for general use at the design stage.

8. Extended fatigue life
An extended fatigue life is considered to be acceptable and within normal design criteria if the calculated fatigue life is longer than the total design life times the Fatigue Design Factor.
Otherwise an extended life may be based on results from performed inspections throughout the prior service life. Such an evaluation should be based on:

1) Calculated crack growth.
Crack growth characteristics; i.e. crack length/depth as function of time/number of cycles (this depends on type of joint, type of loading, and possibility for redistribution of stress).
2) Reliability of inspection method used.
Elapsed time from last inspection performed.
It is recommended to use Eddy Current or Magnetic Particle Inspection for inspection of surface cracks starting at hot spots.

For welded connections that are ground and inspected for fatigue cracks the following procedure may be used for calculation of an elongated fatigue life. Provided that grinding below the surface to a depth of approximately 1.0 mm is performed and that fatigue cracks are not found by a detailed Magnetic Particle Inspection of the considered hot spot region at the weld toe, the fatigue damage at this hot spot may be considered to start again at zero. If a fatigue crack is found, a further grinding should be performed to remove any indication of this crack. If more than 7% of the thickness is removed by grinding, the effect of this on increased stress should be included when a new fatigue life is assessed. In some cases as such as much as 30% of the plate thickness may be removed by grinding before a weld repair is resorted to. This depends on type of joint, loading condition and accessibility for a repair.

It should also be noted that fatigue cracks growing from the weld root of fillet welds can hardly be detected by NDE. Also, the fatigue life of such regions can not be improved by grinding of the surface.

8.1 Fatigue life of in-service structures
Insome structures the welds are machined flush to achieve a high S-N class. Reference is made to Table A.5. It has to be documented that weld overfill has been removed by grinding and that the surface has been proven free from defects. The weld overfill may be removed by a coarse grinder tool such as a coarse grit flapper disk, grit size 40-60. The final surface should be achieved by fine grit grinding below that of weld toe defects. The surface should show a smooth or polished finish with no visible score marks. The roughness should correspond to Ra = 3.2 or better. (It should be remembered that if the area is planned to be coated, a roughness around Ra = 3.2 is often recommended). The surface should be checked by magnetic particle inspection. It is assumed that grinding is performed until all indications of defects are removed. Then possible presence of internal defects in the weld may be a limitation for use of a high S-N class and it is important to perform a reliable non-destructive examination and use acceptance criteria that are in correspondence with the S-N classification that is used.

7.4 TIG dressing
The fatigue life may be improved by TIG dressing by a factor given in Table 7-1.
Due to uncertainties regarding quality assurance of the welding process, this method may not be recommended for general use at the design stage.

7.5 Hammer peening
The fatigue life may be improved by means of hammer peening by a factor given in Table 7-1.

1) The maximum S-N class that can be claimed by weld improvement is C1 or C depending on NDE and quality assurance for execution see Table A-5 in Appendix A.
2) f_y = characteristic yield strength for the actual material.
3) The improvement effect is dependent on tool used and workmanship. Therefore, if the fabricator is without experience with respect to hammer peening, it is recommended to perform fatigue testing of relevant detail (with and without hammer peening) before a factor on improvement is decided.

9. Uncertainties in Fatigue Life Prediction

9.1 General

Large uncertainties are normally associated with fatigue life assessments. Reliability methods may be used to illustrate the effect of uncertainties on probability of a fatigue failure. An example of this is shown in Figure 9-1 based on mean expected uncertainties for a jacket design from "Reliability of Calculated Fatigue Lives of Offshore Structures", ref. /17/.

From Figure 9-1 it might be concluded that a design modification to achieve a longer calculated fatigue life is an efficient mean to reduce probability of a fatigue failure.

The effect of scatter in S-N data may be illustrated by Figure 9-2 where the difference between calculated life is shown for mean S-N data and design S-N data (which is determined as mean minus 2 standard deviations).

The effect of using Design Fatigue Factors (DFF) larger than 1.0 is shown in Figure 9-3. This figure shows the probability of a fatigue failure the last year in service when a structure is designed for 20 years design life. Uncertainties on the most important parameters in the fatigue design procedure are accounted for when probability of fatigue failure is calculated. This figure is derived by probabilistic analysis where the uncertainty in loading is included in addition to uncertainties in S-N data and the Palmgren-Miner damage accumulation rule. (The loading including all analyses of stress is assumed normal distributed with CoV = 25%, Standard deviation = 0.20 in S-N data that is assumed normal distributed in logarithmic scale and the Palmgren-Miner is assumed log normal distributed with median 1.0 and CoV = 0.3).

The same figure also shows the accumulated probability of failure the service life as function of DFF. The accumulated probability of failure is independent of design life (and need not be linked to 20 years service life).

An expected long term stress range is aimed for in the design response analysis. A Design Fatigue Factor equal 1.0 implies a probability of a fatigue crack during service life equal 2.3 % due to the safety in the S-N curve if uncertainties in other parameters are neglected.

Reference is made to Figure 9-3 which shows accumulated probability of a fatigue failure as function of years in service for different assumptions of uncertainty in the input parameters. This figure shows the results for DFF = 1.0. The left part of this figure corresponding to the first 20 years service life is shown in Figure 9-4.

One may achieve results for other values of DFFs by multiplication of the time scale on the abscissa axis by the actual DFF that is considered used.

Figure 9-4 and Figure 9-5 shows accumulated probability of fatigue failure in S-N data corresponding to a standard deviation of 0.20 in log N scale. A normal distribution in logarithmic scale is assumed. The uncertainty in Miner summation is described as log normal with median 1.0 and CoV equal 0.30. Other uncertainties are load and response assumed as normal distributed with CoV 15-20% and hot spot stress derivation also assumed as normal distributed with CoV equal 5-10%.

Calculated fatigue life forms the basis for assessment of probability of fatigue cracking during service life. Thus, it implicitly forms the basis for requirement to in-service inspection, ref. also section 9.2. For details showing a short fatigue life at an early design stage, it is recommended that the considered details are evaluated in terms of improvement of local geometry to reduce its stress concentration. At an early design stage it is considered more cost efficient to prepare for minor geometric modifications than to rely on methods for fatigue improvement under fabrication and construction, such as grinding and hammer peening.

Design Fatigue Factors for different areas should be defined in Company specifications to be used as a contract document for construction.
Figure 9-2
Effect of scatter in S-N data on calculated fatigue life

Figure 9-3
Fatigue failure probability as function of design fatigue factor
9.2 Requirements to in-service inspection for fatigue cracks

Uncertainties associated with fatigue life calculation normally imply that some in-service inspection for fatigue cracks will be required during service life depending on consequence of a fatigue failure and calculated fatigue life. Figure 9-5 may be
used for a first estimate of time to a first inspection based on the lower graph in this figure if normal uncertainties are associated with the fatigue life calculation. Figure 9-5 is derived for a calculated fatigue life equal 20 years. For other calculated fatigue lives \(L_{\text{calc}}\) the numbers on the abscissa axis can be scaled by a factor \(f = L_{\text{calc}}/20\) for estimate of time to first required inspection. If a fatigue crack is without substantial consequences an accumulated probability of \(10^{-2}\) may be considered acceptable and from Figure 9-5 it is not required inspection the first 6 years. If the consequence of a fatigue crack is substantial the accumulated probability of a fatigue failure should be less than \(10^{-4}\) and from Figure 9-5 an inspection would be required after 2 years.

(Normally a calculated fatigue life significantly longer than 20 years would be required for a large consequence connection during design).

After a first inspection the time interval to the next inspection can be estimated based on fracture mechanics and probabilistic analysis taking the uncertainty in the inspection method into account.

Notes on potential modes of failure

In plain steel, fatigue cracks will initiate at the surface, usually either at surface irregularities or at corners of the cross-section. In welded construction, fatigue failure will rarely occur in a region of plain material since the fatigue strength of the welded joints will usually be much lower. In steel with boltholes or other stress concentrations arising from the shape of the member, failure will usually initiate at the stress concentration. The applied stress range shall include applicable stress concentration factors arising from the shape of the member.

Reference is made to section 2.4.10 for non-welded components made of high strength steel with a surface finish Ra = 3.2 or better.

Notes on potential modes of failure

With the weld ends machined flush with the plate edges, fatigue cracks in the as-welded condition normally initiate at the weld toe, so that the fatigue strength depends largely upon the shape of the weld overfill. If the overfill is dressed flush, the stress concentration caused by it is removed, and failure is then associated with weld defects.

Design stresses

In the design of butt welds that are not symmetric about the root and are not aligned, the stresses must include the effect of any eccentricity (see section 3.1 and 3.3).

With connections that are supported laterally, e.g. flanges of a beam that are supported by the web, eccentricity may be neglected.

1. and 2. Details 1. and 2. may be increased to Category C when high quality welding is achieved and the weld is proved free from significant defects by non-destructive examination (it is assumed that this is fulfilled by inspection category I).

1., 2. and 3.

| 1. | All welds ground flush to plate surface parallel to direction of the arrow. |
| 2. | Weld run-off pieces to be used and subsequently removed, plate edges to be ground flush in direction of stress. |
| 3. | All welds welded in horizontal position in shop. |

When the weld is parallel to the direction of the applied stress, fatigue cracks normally initiate at the weld ends. When the weld is transverse to direction of stressing, cracks usually initiate at the weld toe; for attachments involving a single, as opposed to a double, weld cracks may also initiate at the weld root. The cracks then propagate into the stressed member. When the welds are on or adjacent to the edge of the stressed member the stress concentration is increased and the fatigue strength is reduced; this is the reason for specifying an “edge distance” in some of this joints (see also note on edge distance in Table A-3).

1. Welded longitudinal attachment

2. Doubling plate welded to a plate.

3. Longitudinal attachment welded to transverse stiffener.

</tr>
</tbody>
</table>

Notes on potential modes of failure

Failure in cruciform or T joints with full penetration welds will normally initiate at the weld toe. In joints made with load-carrying fillet or partial penetration butt welds, cracking may initiate either at the weld toe and propagate into the plate, or at the weld root and propagate through the weld. In welds parallel to the direction of the applied stress, however, weld failure is uncommon. In this case, cracks normally initiate at the weld end and propagate into the plate perpendicular to the direction of applied stress. The stress concentration is increased, and the fatigue strength is therefore reduced, if the weld end is located on or adjacent to the edge of a stressed member rather than on its surface.

Design stresses

In the design of cruciform joints, which are not aligned the stresses, must include the effect of any eccentricity. The maximum value of the eccentricity may normally be taken from the fabrication tolerances. The design stress may be obtained as the nominal stress multiplied by the stress concentration factor due to the eccentricity.

APPENDIX B
SCF’S FOR TUBULAR JOINTS

B.1 Stress concentration factors for simple tubular joints and overlap joints

Stress concentration factors for tubular joints for joint types T/Y are given in Table B-1, for joint types X in Table B-2, for joint types K in Table B-3 and Table B-4 and for joint types KT in Table B-5. Stress concentration factors are based on “Development of SCF Formulae and Generalised Influence Functions for use in Fatigue Analysis”, ref. /2/.

Joint classification is the process whereby the axial force in a given brace is subdivided into K, X and Y components of actions corresponding to the three joint types for which stress concentration equations exists. Such subdivision normally considers all of the members in one plane at a joint. For purposes of this provision, brace planes within ±15° of each other may be considered as being in a common plane. Each brace in the plane can have a unique classification that could vary with action condition. The classification can be a mixture between the above three joint types.

Figure B-1 provides some simple examples of joint classification. For a brace to be considered as K-joint classification, the axial force in the brace should be balanced to within 10% by forces in other braces in the same plane and on the same side of the joint. For Y-joint classification, the axial force in the brace is reacted as beam shear in the chord. For X-joint classification, the axial force in the brace is carried through the chord to braces on the opposite side. Figure B-1 c), e) and h) shows joints with a combination of classifications. In c) 50% of the diagonal force is balanced with a force in the horizontal in a K-joint and 50% of the diagonal force is balanced with a beam shear force in the chord in a Y-joint. In e) 33% of the incoming diagonal force is balanced with a force in the horizontal in a K-joint with gap 1 and 67% of the incoming diagonal force is balanced with a force in the other diagonal in a K-joint with gap 2. In h) 50% of the diagonal force is balanced with a force in the horizontal on the same side of the chord in a K-joint and 50% of the diagonal force is balanced with a force in the horizontal on the opposite side of the chord in a X-joint.

Definitions of geometrical parameters can be found in Figure B-2.

A classification of joints can be based on a deterministic analysis using a wave height corresponding to that with the largest contribution to fatigue damage. A conservative classification may be used keeping in mind that:

SCFX > SCFY > SCFK.
Figure B-1
Classification of simple joints
Figure B-2
Definition of geometrical parameters.

\[ \beta = \frac{d}{D} \quad \alpha = \frac{2L}{D} \quad \gamma = \frac{D}{2T} \quad \tau = \frac{t}{T} \]

\[ \beta_A = \frac{d_A}{D} \quad \beta_B = \frac{d_B}{D} \quad \beta_C = \frac{d_C}{D} \]

\[ \tau_A = \frac{t_A}{T} \quad \tau_B = \frac{t_B}{T} \quad \tau_C = \frac{t_C}{T} \]

\[ \gamma = \frac{D}{2T} \quad \zeta = \frac{g}{D} \]

\[ \gamma = \frac{D}{2T} \quad \zeta_{AB} = \frac{g_{AB}}{D} \quad \zeta_{BC} = \frac{g_{BC}}{D} \]
The validity range for the equations in Table B-1 to Table B-5 is as follows:

\[
0.2 \leq \beta \leq 1.0 \\
0.2 \leq \tau \leq 1.0 \\
8 \leq \gamma \leq 32 \\
4 \leq \alpha \leq 40 \\
20^\circ \leq \theta \leq 90^\circ \\
-0.6\beta \sin\theta \leq \zeta \leq 1.0
\]

Reference is made to Section 4.2 if actual geometry is outside validity range.

<td></td>
</tr>
</tbody>
</table>
It should be noted that equations (6b) and (7b) will for general load conditions and moments in the chord member provide correct hot spot stresses at the crown points while equations (6a) and (7a) only provides correct hot spot stress due to a single action load in the considered brace. Equations (6b) and (7b) are also more general in that a chord-fixation parameter need not be defined. In principle it can account for joint flexibility at the joints when these are included in the structural analysis. Also the upper limit for the $\alpha$-parameter is removed with respect to validity of the SCF equations. Thus, these equations are in general recommended used.

Equation (6a) and (6b) will provide the same result only for the special case with a single action load in the considered brace and $SCF_{att} = 1.0$. For long chords the brace can be considered as an attachment to the chord with respect to axial stress at the crown points. This would give detail category F from Table A-7 (for thick braces and E-curve for thinner) which corresponds to $SCF_{att} = 1.27$ from Table 2-1.

#### Out-of-plane bending on one brace only

Chord SCF adjacent to diagonal brace A:

\[
(Eqn. (10))_A \cdot \left( 1 - 0.08 (\beta_B \gamma)^{0.5} \exp(-0.8 \chi_{AB}) \right) \left( 1 - 0.08 (\beta_C \gamma)^{0.5} \exp(-0.8 \chi_{AC}) \right)
\]

where

\[
\chi_{AB} = 1 + \frac{\zeta_{AB} \sin \theta_A}{\beta_A}
\]

\[
\chi_{AC} = 1 + \frac{(\zeta_{AB} + \zeta_{BC} + \beta_B) \sin \theta_A}{\beta_A}
\]

(Eqn. (30))

Chord SCF adjacent to central brace B:

\[
(Eqn. (10))_B \cdot \left( 1 - 0.08 (\beta_A \gamma)^{0.5} \exp(-0.8 \chi_{AB}) \right) \left( 1 - 0.08 (\beta_C \gamma)^{0.5} \exp(-0.8 \chi_{BC}) \right)
\]

where

\[
\chi_{AB} = 1 + \frac{\zeta_{AB} \sin \theta_B}{\beta_B}
\]

\[
\chi_{BC} = 1 + \frac{\zeta_{BC} \sin \theta_B}{\beta_B}
\]

\[
P_1 = \left( \frac{\beta_A}{\beta_B} \right)^2
\]

\[
P_2 = \left( \frac{\beta_C}{\beta_B} \right)^2
\]

(Eqn. (31))

Out-of-plane brace SCFs are obtained directly from the adjacent chord SCFs using:

\[
\tau^{-0.54} \gamma^{-0.05} \left( 0.99 - 0.47 \beta + 0.08 \beta^4 \right) \text{SCF}_{\text{chord}}
\]

(Eqn. (32))
APPENDIX C
SCF’S FOR PENETRATIONS WITH REINFORCEMENTS

C.1 SCF’s for small circular penetrations with reinforcement

C.1.1 General

Stress concentration factors at holes in plates with inserted tubulars are given in Figure C-1 - Figure C-15.
Stress concentration factors at holes in plates with ring reinforcement are given in Figure C-16 - Figure C-20.
Stress concentration factors at holes in plates with double ring reinforcement given in Figure C-21 - Figure C-24.
The SCFs in these figures may also be used for fatigue assessments of the welds. Stresses in the plate normal to the weld, $\Delta\sigma_n$, and stresses parallel to the weld, $\Delta\tau_{//}$, in equation 3.1.4 may be derived from the stresses in the plate. The total stress range, $\Delta\sigma_{tot}$, from equation 3.1.4 (or from equation 2.3.4) is then used together with the W3 curve to evaluate number of cycles until failure.

C.1.2 Example of fatigue analysis of a welded penetration in plate

A tubular $\Phi 800 \times 15$ is used as a sleeve through a deck plate of thickness 20 mm. The tubular will be welded to the deck plate by a double sided fillet weld.

Assume Weibull parameter $h = 0.90$ and that the deck has been designed such that S-N class F3 details can be welded to the deck plate and still achieves a fatigue life of 20 years. From Table 5-2 a maximum stress range of 199.6 MPa during $10^8$ cycles is derived for the F3 detail.

Questions asked:
1) Is the fatigue life of the penetration acceptable with respect to fatigue cracking from the weld toe?
2) How large fillet weld is required to avoid fatigue cracking from the weld root?

The following assessment is made: $v/t_p = 20$, $t_p/t_{weld} = 0.75$. It is assumed that $H/t_{weld} = 5$. Then from:

Figure C-4 SCF = 2.17 applies to position Figure 3-4 a.
Figure C-7 SCF = 0.15 applies to position Figure 3-4 c and weld root.
Figure C-10 SCF = 1.07 applies to position Figure 3-4 b and weld toe.
Figure C-12 SCF = 0.46 applies to position Figure 3-4 b and weld root.
Figure C-14 SCF = -0.75 applies to position Figure 3-4 b and weld toe.

A negative SCF value in some of the figures means that the resulting stress is negative at the hot spot for a positive stress in the plate. Thus for fatigue assessment the absolute value should be used.

The C-curve applies to position Figure 3-4 a.
The D-curve applies to weld toes of Figure 3-4 b.
The W3-curve applies to weld root of Figure 3-4 c.

Check of fatigue cracking at the Figure 3-4 a position:
$\Delta\sigma = \Delta\sigma_0 \times SCF = 199.6 \times 2.17 = 433.13$ MPa which is just within the acceptable value of 445.5 MPa for a C detail, ref. Table 5-2.

Check of fatigue cracking at the Figure 3-4 a b position:
$\Delta\sigma = \Delta\sigma_0 \times SCF = 199.6 \times 1.07 = 213.57$ MPa which is well within the acceptable value of 320.8 MPa for a D detail, ref. Table 5-2.

Thus the fatigue life of weld toe is acceptable.

The required throat thickness is calculated as follows. From Table 5-2 a maximum stress range of 128.2 MPa for a W3 detail (Weibull shape parameter $= 0.90$).

Then from considerations of equilibrium in direction normal to the weld toe:

$$\Delta\sigma_n = \sigma_{nominal} \times SCF = 199.6 \times 0.15 = 29.94$$

From considerations of equilibrium in direction parallel with the weld toe:

$$\tau_{//} = \sigma_{nominal} \times SCF = 199.6 \times 0.46 = 91.82$$

Then from equation (3.1.4):

$$128.2 = \frac{20}{2a} \sqrt{(29.94)^2 + 0.2 (91.82)^2}$$

From this equation a required throat thickness is $a = 4.0$ mm for both sides of the plate. This is a required weld size that is well below the minimum required weld size specified in ship classification rules.
C.1.3 SCF’s for small circular penetrations with reinforcements

Figure C-1
SCF at hole with inserted tubular. Stress at outer surface of tubular, parallel with weld. H/tr = 2

C.2.1 Geometry

The following hole geometries are considered see also Figure C-25:

1) Circular cut-out with diameter = 600 mm
2) Rectangular cut-out 600 x 800 mm with rounded corner R = 300 mm
3) Rectangular cut-out 600 x 1200 mm with rounded corner R = 300 mm

![Cut-out geometries](image)

For the three cut-out geometry six different edge reinforcements are applied, see Figure C-26. The reinforcement details are described below, see also Figure C-26:

(A) Cut-out alone (no reinforcement) (Figure C-26 (A))
(B) Cut-out with inserted plate (15 mm thick, 300 mm wide) around the edge (Figure C-26 (B))
(C) Cut-out with double side reinforcement 50 mm away from the edge (Figure C-26 (C))
(D) Cut-out with single side reinforcement 50 mm away from the edge (Figure C-26 (D))
(E) Cut-out with double side reinforcement 100 mm away from the edge (Figure C-26 (E))
(F) Cut-out with single side reinforcement 100 mm away from the edge (Figure C-26 (F))

Stress concentrations factors are presented for the hot-spots marked in Figure C-26.

![Reinforcement positions](image)

For geometry (D) and (F), the maximum stresses of the bottom or the top surface in the 20 mm plate at the cut-out edge are given in the plots. For the other geometry the stresses are symmetrical about the mid-plane of the plate.
C.2.2 Applied stresses
The following stresses has been considered:
— longitudinal stress, $\sigma_x$
— transverse stress, $\sigma_y$
— shear stress, $\tau$

The stresses in the longitudinal and the transverse directions are applied separately but are combined with shear stress. The shear stress is varied between zero and up to the value of the normal stress.

C.2.3 Stress Concentration Factor Definition
The definition of the stress concentration factors presented for cut-outs are the maximum principal stress divided by the nominal normal stress, $\sigma_x$ or $\sigma_y$, (not the nominal principal stress). The maximum principal stress in the hot-spot is selected as the maximum of $|\sigma_1|$ and $|\sigma_2|$. The stress concentration factor ($K_g$) is then:

$$K_{g,x(y)} = \frac{\max(|\sigma_1|,|\sigma_2|)}{\sigma_{x(y)}}$$

C.3 Results
In general, stress concentration factors are given at 5 points (see Figure C-26) except for the cases shown in Figure C-26 (A) and (B).

The following should be noted:

— Maximum principal stresses are parallel to the weld toe (hot-spots 2 to 5) with only one exception: for double reinforcement and point 2 (see Figure C-26,(C) and (E)), the maximum principal stress is normal to the weld toe.

### APPENDIX D

#### COMMENTARY

**D.1 Comm. 1.2.3 Low cycle and high cycle fatigue**

By fatigue strength assessment of offshore structures is normally understood capacity due to high cycle fatigue loading.

By high cycle loading is normally understood cycles more than 10,000. For example stress response from wave action shows typically 5 million cycles a year. A fatigue assessment of response that is associated with number of cycles less than 10,000 is denoted low cycle fatigue.

This Recommended Practice is mainly made with the purpose of assessing fatigue damage in the high cycle region. The specified S-N curves are shown in the graphs above 10^4 cycles. Typical S-N test data are derived for number of cycles between 10^4 and 5 * 10^6 cycles. However, the S-N curves may be linearly extrapolated to fewer cycles for practical use in fatigue assessment. This is not necessarily conservative and in case of a high utilisation the approach described in Norsok N-006 may be used.

High cycle fatigue analysis is based on calculation of elastic stresses that are used in the assessment.

Low cycle fatigue is associated with load reversals that imply significant yielding at the hot spot during the load reversal. Therefore calculated strain is often used as a parameter to account for non-linear material behaviour when low cycle fatigue is considered.

Offshore structures are normally designed for other limit states such as the Ultimate Limit State (ULS). Then a load and material coefficient is used in design to achieve sufficient safety. Even if stresses due to local notches are not accounted for in an ULS design the assessment of ULS implies that the actual strain ranges during an ULS loading is limited and that a further assessment of low cycle fatigue is normally not required. Thus for design of offshore structures in the North Sea it has in general not been practice to analyse the structures specifically for low cycle fatigue.

When non-linear methods are used for documentation of ULS e.g. for a storm loading on a platform, it is recommended to assess low cycle fatigue during that considered storm. Reference is made to Norsok N-006 for further guidance.

Low cycle fatigue is also found to be of concern in some local areas in ship structures due to loading and unloading. The reason for this is that ship structures in general show a much higher utilisation in ULS than offshore structures.

FPSOs are rather similar structures with similar loading and unloading as tankers; therefore low cycle fatigue may be an issue to consider for these structures depending on procedure used for loading and unloading.

For calculation of fatigue damage at highly loaded details it is recommended to calculate a stress range from the wave action corresponding to the largest expected stress range during the time interval of a loading/unloading cycle. This stress range should be added to the low cycle stress range before the fatigue damage from the low cycle fatigue is calculated. This stress range from the wave action can be calculated as

\[
\Delta \sigma_v = \Delta \sigma_0 \left(1 - \frac{\log n_{LCF}}{\log n_0}\right)^{1/h}
\]

where

- \(\Delta \sigma_0\) = largest stress range corresponding to \(n_0\) cycles from wave action
- \(n_{LCF}\) = number of loading/unloading cycles during the lifetime

\[h = \text{Weibul shape parameter from the wave action.}\]

Then an effective stress range to be used for calculation of low cycle fatigue can be obtained as

\[\Delta \sigma_v = \Delta \sigma_{LCF} + \Delta \sigma_w\]

This effective stress range is used for calculation of fatigue damage from low cycle fatigue: \(D_{LCF}\). Then the resulting fatigue damage can be calculated as the sum

\[D = D_{LCF} + D_{HCF}\]

where \(D_{HCF}\) is fatigue damage from the wave action alone.

Due to large stress cycles implying local yielding at the hot spot the calculated stress range from a linear elastic analysis should be modified by a plasticity correction factor before the S-N curve is entered for calculation of fatigue damage, ref. e.g. Norsok N-006.

**D.2 Comm. 1.3 Methods for fatigue analysis**

#### Important part of action history

The contribution to fatigue damage for different regions of a Weibull distribution is shown in Figure D-1 for fatigue damage equal 1.0 (and 0.5) for a 20-year period. The calculation is based on a Weibull long term stress range distribution with shape parameter \(h = 1.0\) (in the range that is typical for a semi-submersible and an S-N curve with slope \(m = 3.0\) for \(N < 10^7\) and \(m = 5.0\) for \(N > 10^7\) cycles (Typical S-N curve for air condition).

It is noted that the most important part of the long-term stress range is for actions having a probability of exceedance in the range \(10^{-3}\) to \(10^{-1}\). This corresponds to \(\log n = 5-7\) in Figure D-1.

**D.3 Comm. 2.2 Combination of fatigue damages**

#### from two dynamic processes

**Background**

In some design cases one fatigue damage is calculated for one dynamic process. Then another fatigue damage for the same hot spot is calculated for another dynamic process. Then the question arises on how to calculate the resulting fatigue damage for the considered hot spot. It is non-conservative to sim-
ply add the two fatigue damages together.

An example of such a design situation is swell response of an FPSO that also is subjected to wind response.

Another example may be wave response of a floating platform that also may be subjected to wave response on a flare tower that are giving stress cycling at the same hot spot in the structure. In many cases it is practical to calculate the fatigue damage for each of these processes separately as the design may belong to different engineering contracts.

When a detailed stochastic analysis of the complete structural system is performed for each of the dynamic processes a more accurate combined stress response can be calculated before the S-N curve is entered and the fatigue damage is calculated. Ref. for example DNV-OS-E301 Position Mooring, June 2001.

In the following a simple method for derivation of resulting fatigue damage from two processes is presented. This methodology is based on information of mean zero up-crossing frequency in addition to the calculated fatigue damages for each of the processes.

**Combined fatigue damage for one slope S-N curve**

Combined fatigue damage for the responses shown in Figure D-2 can be obtained as

\[
D = D_1 (1 - \frac{\nu_2}{\nu_1}) + \nu_2 \left( \frac{D_1}{\nu_1}^{1/m} + \frac{D_2}{\nu_2}^{1/m} \right)^m
\]

(D.3-1)

where

- \(D_1\) = calculated fatigue damage for the high frequency response
- \(D_2\) = calculated fatigue damage for the low frequency response
- \(\nu_1\) = mean zero up crossing frequency for the high frequency response
- \(\nu_2\) = mean zero up crossing frequency for the low frequency response
- \(m\) = inverse slope of the S-N curve = 3.0.

The combined fatigue damage is based on the assumption that each of the fatigue damages \(D_1\) and \(D_2\) are derived based on a one slope S-N curve. The equation is derived based on analogy with Rainflow stress range counting.

**Combined fatigue damage for two-slope S-N curves**

For two-sloped S-N curves it is questioned if equation (D.3-1) can be used for calculation of resulting fatigue damage.

The S-N curves in air have a transition in slope from \(m = 3.0\) to \(m = 5.0\) at 10^7 cycles.

For a long term stress range distribution with Weibull shape parameter \(h = 1.0\), 20 years service life, and a fatigue damage equal 1.0 the major contribution to fatigue damage occurs around 10^7 cycles. Approximately half the damage occurs at number of cycles below 10^7 cycles and the other half above 10^7 cycles. For lower fatigue damage than 1.0, which is the case in order to have acceptable resulting fatigue damage when considering two processes, the main contribution to fatigue damage will be at the S-N line with slope \(m = 5.0\).

Thus, in order to have a methodology that is safe one should use a slope \(m = 5.0\) in equation (D.3-1) if the fatigue damages for the two processes have been calculated based on this two-slope S-N curve.

An alternative to this is to calculate the fatigue damage for process no 2 with a straight S-N curve with slope \(m = 3.0\). Then equation (D.3-1) can be used with \(D_1\) calculated from a two-slope S-N curve and with \(m = 3.0\).

**D.4 Comm. 2.3.2 Plated structures using nominal stress S-N curves**

The fatigue capacities of welded connections are dependent on the principal stress range direction relative to the weld toe. The following guidance is based on assessment of fatigue test data. Figure D-3 a) and b) are intended used for nominal stress analyses.

The selection of E or F curve for \(\phi = 0^\circ\) depends on thickness of attachment as presented in Table A-7 in Appendix A. For other \(\phi\) values see Table D-1.

Figure D-3 c) can be used together with the hot spot stress methodology in general.

In general the stress range in both the two principal directions shall be assessed with respect to fatigue.

* A higher S-N curve may be used in special cases. See Table A-3 for further information.
A main reason for this is lack of relevant fatigue test data for derivation of S-N curves as expressed in some literature than that expressed by simple mathematical regression of the S-N curve is required for purpose of probabilistic analysis. It is more complex to derive design S-N curves for real structures than that of ideal structures. Thus, also engineering assessment is required for derivation of recommended design S-N curves in a design standard that can be used to achieve sound structures with respect to fatigue capacity.

One specific S-N curve may be used for different details. In principle different details can show different scatter when they are tested. The simple details show less scatter in test data than the more complex details.

Fatigue testing is normally performed under constant amplitude loading while actual structures are likely subjected to variable amplitude loading. This introduces additional uncertainty as explained in section 2.4.13.

All this makes it difficult to present standard deviations that are representative for each specific S-N curve. However, without having test data made for a specific design and fabrication a typical standard deviation \( \sigma_{\log N} \approx 0.20 \) can be used for all the S-N curves in sections 2.4.4 to 2.4.9 and 2.4.11. \( \sigma_{\log N} \approx 0.162 \) can be used for the high strength S-N curve in section 2.4.10. \( \sigma_{\log N} \approx 0.225 \) can be used for the S-N curve for umbilical pipes in section 2.4.12.

### Size effect

The size effect may be explained by a number of different parameters:

- thickness of plate – which is explained by a more severe notch with increasing plate thickness at the region where the fatigue cracks are normally initiated
- attachment length – which is explained by a more severe notch stress due to more flow of stress into a long attachment than a short
- volume effect – which for surface defect can be explained by increased weld length and therefore increased possibility for imperfections that can be initiated into fatigue cracks.

It might be added that some authors group all these three effects into one group of “thickness effect” or size effect. In this Recommended Practice, the thickness exponent is assumed to cover the first item in the list above and partly the second, although also an increased attachment length reduces the S-N class as shown in Appendix A of this Recommended Practice. Examples of the third effect and how it can be accounted for in an actual design is explained in more detail in the following. Reference may also be made to /12/, /19/ and /18/ for more background and explanation of the thickness effect.

Test specimens used for fatigue testing are normally smaller than actual structural components used in structures. The correspondence in S-N data depends on the stress distribution at the hot spot region. For traditional tubular joints there is one local hot spot region, while at e. g. circumferential welds of TLP tethers there is a length significantly longer than in the test specimens having the similar order of stress range. Crack growth is normally initiated from small defects at the transition zone from weld to base material. The longer the weld, the larger is the probability of a larger defect. Thus, a specimen having a long weld region is expected to have a shorter fatigue life than a short weld. This can be accounted for in an actual design by probabilistic analysis of a series system, ref. e. g. “Methods of Structural Safety” ref /21/. Weld length in a tether system is one example where such analysis should be considered to achieve a reliable fatigue design. A mooring line consisting of chains is another example where reliability methods may be used to properly account for the size effect or system effect.

---

D.5 Comm. 2.4.3 S-N curves and joint classification

Normally the standard deviation of the log N is not required for design purpose as the design S-N curves are presented as mean-minus-two-standard-deviations as described in section 2.4.1. However, information about the standard deviation in the S-N curve is required for purpose of probabilistic analysis. It is more complex to derive design S-N curves for real structures than that expressed by simple mathematical regression of test data for derivation of S-N curves as expressed in some literature. A main reason for this is lack of relevant fatigue test data for structures. Most of the fatigue test data are derived from testing of small scale test specimens. These specimens do not include the same amount of residual stresses as a full scale structure. The test data may also belong to different R-ratios. Further, the small scale test specimens are most often more perfect considering tolerances and defects than that of real structures. Thus, also engineering assessment is required for derivation of recommended design S-N curves in a design standard that can be used to achieve sound structures with respect to fatigue capacity.

---

Figure D-3
Classification of details and selection of S-N curve

---

DET NORSKE VERITAS
The system effect for the S-N curves in this RP has been investigated using reliability methods. The results are expressed analytically below.

The length of weld and number of similar connections subjected to the same stress range should be assessed based on engineering judgement. If a tether system is subjected to a dynamic axial force without significant bending the assessment becomes simple as all welds will be subjected to the same stress range. As soon as there is some bending over the diameter of the tether there will likely be some hot spots at some connections that are subjected to a larger stress range than the other connections. Then only the regions with the most severe stress ranges need to be included for weld length and number of connections.

For threaded bolts, the stress concentration at the root of the threads increases with increasing diameter. Based on fatigue tests, it is recommended to use \( k = 0.25 \) which can be assumed to include size effects both due to the notch itself, and due to increased length of notch around circumference with increased diameter. The thickness exponent may be less for rolled threads. Thus for purpose made bolts with large diameters, it may be recommendable to perform testing of some bolts to verify a fatigue capacity to be used for design. It should be remembered that the design S-N data is obtained as mean minus 2 standard deviation in a log S-log N diagram.

**S-N curve with thickness effect**

The design S-N curve with thickness effect included is given by:

\[
\log N = \log \bar{a}_1 - m_1 k \log \left( \frac{t}{t_{\text{ref}}} \right) - m_1 \log \Delta \sigma \quad (D.5-1)
\]

Part (2) of the curve is established assuming continuity at \( N_1 = 10^6 \) or \( 10^7 \) cycles depending on the S-N curve is given for seawater with cathodic protection or in air is given by

\[
\log N = \frac{m_2}{m_1} \log \bar{a}_1 - m_2 k \log \left( \frac{t}{t_{\text{ref}}} \right) - m_2 \log \Delta \sigma \quad (D.5-2)
\]

where \( \bar{a}_1 \) is for S-N curve without thickness effect included. \( \bar{a}_1 \) is given in Table 2-1, 2-2 and 2-3.

Part (2) of the S-N curve can also be written on a standard form

\[
\log N = \log \bar{a}_2 - m_2 k \log \left( \frac{t}{t_{\text{ref}}} \right) - m_2 \log \Delta \sigma \quad (D.5-3)
\]

where

\[
\log \bar{a}_2 = \frac{m_2}{m_1} \log \bar{a}_1 + \left( 1 - \frac{m_2}{m_1} \right) \log N_1 \quad (D.5-4)
\]

**S-N curve with system effect and thickness effect**

The design S-N curve with system effect and thickness effect included is given by:

\[
\log N = \log \bar{a}_3 - m_3 k \log \left( \frac{t}{t_{\text{ref}}} \right) - m_3 \log \Delta \sigma \quad (D.5-5)
\]

where

\[
\bar{a}_3 = \left( \frac{t_{\text{weld}}}{t_{\text{ref}}} \right)^{s_{\log N}} \left( \frac{t_{\text{ref}}}{t_{\text{ref}}} \right)^{s_{\log N}} - m_1 \log \Delta \sigma \quad (D.5-6)
\]

with

\[
\log \bar{a}_3 = \frac{m_1}{m_1} \left( \log \bar{a}_1 - m_1 \log \Delta \sigma \right) + \left( 1 - \frac{m_1}{m_1} \right) \log N_1 \quad (D.5-7)
\]

where \( \bar{a}_1 \) is for S-N curve without thickness effect included. \( \bar{a}_1 \) is given in Table 2-1, 2-2 and 2-3.
Link to S-N curves in other design codes

The relationship between S-N curves in this document and those given by IIW, ref. /30/, Eurocode 3, ref. /3/, for air environment is given in Table D-1. It should be noted that the correspondence between S-N curves in this document and IIW relates only to number of cycles less than 5·10⁶ in Eurocode 3.

D.6 Comm. 2.4.9 S-N curves and efficiency of corrosion protection

S-N curve for joints in the splash zone

In Norway it has been the practice to use seawater S-N curve with cathodic protection for joints in the splash zone and a larger Design Fatigue Factor (DFF) in the splash zone than in other areas in jacket structures. It is assumed that the joints also have a good coating.

A high DFF is used because it is considered to be difficult to perform inspection and repair in this area. Increasing the DFF implies that the probability of a fatigue cracking becomes reduced. For example a DFF = 10 implies that the probability of a fatigue crack during the lifetime becomes very small (accumulated probability less than 10⁻⁴ and annual less than 10⁻³ the last year in service).

Quite a lot of the fatigue life is associated with initiation of a fatigue crack and growth of small cracks. The cracks have to grow to some size before the coating is broken. As long as the coating is not broken the condition corresponds to that of air.

The probability of having a fatigue crack that is so large that the coating is broken is considered to be low within the major part of the design life using a DFF = 10.

Based on this it is considered acceptable to calculate fatigue damage with an S-N curve that is somewhat reduced compared with that of air. Then the seawater curve with cathodic protection can be used in lack of documented S-N curves in seawater in free corrosion for coated joints (in the high cycle region above 10⁶ cycles).

This recommendation is linked to use of a high DFF and a good coating. Then the probability of presence of an open fatigue crack subjected to free corrosion becomes small in the major part of the service life of the platform life as explained above.

S-N curve for details in tanks in FPSOs

Tanks in FPSOs are not designed with the same high DFF as used for splash zone joints in jackets. Also the coating is not so durable. The coating becomes more brittle with time and it is most likely to crack at hot spot regions with large strain cycles. In tanks without anodes the efficiency of the coating should be
specially considered.

In DNV Classification Note No. 30.7 it is assumed that the coating is efficient for some years and then the condition is that of free corrosion. A similar procedure may be used for design of tanks in FPSOs. The time with efficient coating depends on type and quality of the coating used. Reference is made to DNV Classification Note No. 30.7 for more details.

D.7 Comm. 2.4.13 Qualification of new S-N curves based on fatigue test data

Effect of residual stresses

The residual stresses at weld toes of small scale test specimens are normally small as compared with that in actual full size structures due to different restraints during fabrication. Also if small scale test specimens are produced from cutting from larger structures a significant part of the residual stresses will likely be lost. This should be kept in mind when planning the testing and when assessing the test results in terms of an S-N curve.

A reduced residual stress in the test specimens may be compensated for by performing the testing at a high R-ratio. (By a high R-ratio is understood R = σ_min/σ_max around 0.5 and low R-ratio in region 0 to 0.1). As the maximum nominal stress is limited by the yield of the material it is easier to achieve a high R-ratio for the longer fatigue lives where a low stress range is expected than for the short fatigue lives. This may lead to testing at R-ratios that are not constant within one test series. This may be different from earlier practice; however, this is considered to be fully acceptable. Another approach that has been followed to derive design S-N curves for welded structures based on fatigue test data from small scale test specimens has been to force the curves through the centre of gravity of the test data with a predefined logarithmic format. This gives reduced requirements to c values to be used in equation (D.7-1).

Statistical assessment of fatigue test data

To plan fatigue testing that will provide a reliable basis for derivation of design S-N curves requires experience from fatigue assessment of structures and knowledge about statistics. Some guidance can be found in literature such as ISO 12107 “Metallic materials – fatigue testing – Statistical planning and analysis of test data”. However, engineering judgement is required in each case to specify type of test specimen, number of tests and loading to be used in the tests. Engineering judgement is also required for assessment of recommended slope in S-N curve to be used for fatigue assessment of real structures as compared with that derived from small scale test specimens due to difference in residual stresses at the hot spots.

A design S-N curve should provide a 97.7% probability of survival. The design curves can be derived as mean minus two standard deviations as obtained from a plot of experimental data assuming the data to follow a Gaussian distribution in a logarithmic format.

The statistical uncertainty in fatigue test data shall be accounted for when a limited number of tests is performed to establish design S-N curves. It is required that the mean curve is estimated with at least 75% confidence. When a total of n fatigue tests carried out at the same representative stress range S, then the characteristic value of the design S-N curve can be derived as:

\[ \log a = \log \bar{a} - c s_{\log N} \]  

(D.7-1)

where

\[ \log a = \text{intercept of the mean value of the n test data with the log N axis} \]

\[ s_{\log N} = \text{the standard deviation of the n test data of log N, and} \]

\[ c \text{ is a factor whose value depends on number of fatigue test data and is shown in Table D-3 and Figure D-5 for the case where the standard deviation is “known” and also when it is “unknown”}. \]

A derivation of a design S-N curve may follow different approaches. It may be useful to understand the difference between the following two approaches:

- Pure statistical approach
- Engineering approach

By following a pure statistical approach a mean S-N curve and a standard deviation of test data can be derived. This corresponds to standard deviation being unknown when determining c values in Table D-3 and Figure D-5 to be used in equation (D.7-1). This requires a significant number of test specimens (as seen from the figure). This recommendation is sometimes used in small scale testing but can hardly be afforded when performing more full scale type testing.

When doing a lot of testing that result in much the same values of standard deviations, one can assume the standard deviation as known. Thus the main challenge is to derive mean values. This gives reduced requirements to c values to be used in equation (D.7-1). This may also be seen as an engineering approach that one may consider using in well defined tests (instrumented full scale type testing). For standard deviation from fatigue test data see commentary section 2.4.3.

For complex connections a larger standard deviation can be expected. It should be checked that that the fatigue test data looks homogeneous and that the scatter is not larger than that normally observed in fatigue testing.

It should be added that a few large scale tests can add significant confidence to a design S-N curve dependent on type of structural detail to be designed. A prototype test specimen that is fabricated in a similar way as the actual connection is considered to represent a physical behaviour in a representative manner as it is similar in geometry, material characteristics, residual stress, and fabrication tolerances. In addition it can likely be subjected to a more relevant loading as compared with that of small scale test specimens. Thus, even if only one large scale test is performed, it is reasonable to put as much significance into that test result as can be substantiated by a total engineering judgement rather than a statistical assessment.

An engineering assessment may also take knowledge from performed analysis into account. This assessment may depend on how the analysis has been performed and thus safety inherent the procedure that is used, ref. section 5.4.

Table D-3 Number of standard deviations to be subtracted from the mean to derive a design S-N curve with 97.7 % probability of survival
Justifying the use of a given design curve from a new data set

This section presents a methodology to validate the use of a particular design S-N class on the basis of a limited number n of new fatigue tests. It is assumed that the design S-N curve is described on a form as presented in section 2.4 and that the standard deviation in the S-N curve is known.

It is assumed that the fatigue testing is performed until a well defined failure is achieved such as a fatigue crack through the considered design S-N curve for the new test data can be established. A mean S-N curve based on the new test data can be derived as

$$log N = log a - m \log(\Delta \sigma SMF) + \frac{x_c}{\sqrt{n}} s_{log N} \quad \text{(D.7-2)}$$

where

- $N$ = number of cycles (mean value of new test data at stress range $\Delta \sigma$)
- $log a$ = Intercept of considered mean standard S-N curve in this RP with the log N axis
- $m$ = slope of standard S-N curve
- $\Delta \sigma$ = stress range
- SMF = Stress Modification Factor
- $n$ = number of test samples
- $x_c$ = confidence with respect to mean S-N data as derived from a normal distribution
- $x_c = 0.674$ for 75% confidence level and 1.645 for 95% confidence level.
- $s_{log N}$ = standard deviation in the standard S-N curve

From the equation above the SMF can be derived as

$$SMF = \frac{(log a - \log N - m \log \Delta \sigma + 0.674 \sqrt{n} s_{log N})/m}{n} \quad \text{(D.7-3)}$$

and with $n$ fatigue test data to derive mean S-N curve from these data

$$SMF = \frac{(log a - \sum_{i=1}^{n} \log N_i - m \sum_{i=1}^{n} \log \Delta \sigma_i + 0.674 \sqrt{n} s_{log N})/m}{n} \quad \text{(D.7-4)}$$

Then a revised design S-N curve can be derived as

$$log N = log a - 2 s_{log N} - m \log(\Delta \sigma SMF) \quad \text{(D.7-5)}$$

or

$$log N = log a - 2 s_{log N} - m \log SMF - m \log(\Delta \sigma)$$

**Example of analysis case A:**

Assume testing of connectors with test data as shown in Table D-4. It is assumed that the test data follow a shape of the S-N curve similar to the high strength curve in section 2.4.10 with $m = 4.7$. The test data are presented in Figure D-6 together with the mean curve derived from the 6 test results and design S-N curve derived from the same test data. It is assumed that the testing is performed in the order as listed in Table D-4 from S1 to S6. In principle one may assume the testing to be stopped after any number of the tests and perform an assessment of resulting SMF. This is done in this example in the following.

Stress modification factors (SMFs) derived from statistics using a student t distribution and considering standard deviation as unknown is shown in Table D-4 and Figure D-7. SMFs derived from equation (D.7-4) by considering the standard deviation as known is also shown in Table D-4 and Figure D-7. The present data set (from all 6 tests) shows a resulting standard deviation equal 0.161 in log $N$. The standard deviation in the high strength S-N curve as presented in section 2.4.10 is 0.162. This standard deviation is derived from testing of the base material only. Thus, if one considers uncertainty in actual fabrication, fabrication tolerances and make-up torque, it is likely that a larger standard deviation should be used. This may be assessed based on general fatigue test data of such connections, if available. (See also Example case B below).

Based on this example it is seen that a few tests may provide very useful information about the fatigue design procedure. Even only one test may provide to give very useful information and estimate of SMF to be used for design. The recommended number of tests will in principle be somewhat dependent on the test results from the first tests that are performed. If one plot the test results in a graph like that shown in Figure D-7 one can judge the convergence in derived SMF factor before one decide on further testing. In this example it is seen that a significant confidence in the estimated SMF is achieved after the first 3 tests.

It is observed from Table D-4 that if the testing is stopped after the two first tests $(S1+S2)$ a SMF equal 5.22 is derived. After three tests $(S1+S2+S3)$ the SMF is changed to 5.10 which is not very far from the SMF derived after 6 tests in this example. If one plot the test results in a graph like that shown in Figure D-7 one can judge the convergence in derived SMF factor before one decide on further testing. In this example it is seen that a significant confidence in the estimated SMF is achieved after the first 3 tests.

Tables for student t distributions can be found in statistical handbooks, Ang and Tang, DNV-RP-C207 and also from spreadsheets.

Figure D-6
Test data used for derivation of SMF in example (St. dev 6 test data = 0.161)

Figure D-7
SMF factor as function of number of test specimens (St. dev 6 test data = 0.161) (By one test is understood test S1 in Table D-4, by 2 tests is understood S1 and S2, etc).
Example of analysis case B:
This example is made to check the robustness of the proposed analysis procedure. The test data from Table D-4 is modified in a fictitious manner such that the scatter is significantly increased by approximately doubling the standard deviation to 0.318 for the 6 test data. The mean S-N curve from the test data is kept the same as in example case A. In addition the ordering of the test data is changed into a worst situation with the first tests furthest away from the basis high strength S-N curve; see also Figure D-8 and Figure D-6.

The SMF from the student t distribution includes the actual calculated standard deviation after 2, 3 tests etc. Test number 6 falls significantly outside the mean S-N curve which increases the standard deviation significantly. This explains the SMF based on student t after 6 tests as compared with 5 tests (Table D-5 and Figure D-9).

First it is assumed that the standard deviation in the new test data follow that of the high strength steel curve (with standard deviation equal 0.162 while the calculated standard deviation for the 6 test data is 0.318). The effect of assuming different confidence levels for this assumption is illustrated in Figure D-9. The difference in calculated SMF is not that large for different confidence levels.

The resulting SMFs are also shown in Table D-5 and Figure D-9 when the standard deviation in equation (D.7-4) is increased to 0.318 (for 75% confidence level). It is observed that this results in a higher SMF. This illustrates that one should try to use a relevant value of an expected (or conservative) standard deviation into equation (D.7-4).

From Figure D-9 it is seen that the calculated SMF reduces with number of test data. This effect is likely augmented due to the sequence of the test data used in this fictitious example which is less likely to be similar to this example at least for more test data than 3 to 4.

From the example in Figure D-9 one might get the impression that it is conservative with one test. However, the resulting decrease of SMF with number of tests is a result of sequence of the test data used. Another case could be to present the test data in a reversed order. This would results in the lowest calculated SMF for one test and a slightly increasing SMF with including additional number of tests as is shown in Figure D-10.

Figure D-8
Test data used for derivation of SMF in example (St. dev 6 test data = 0.318)
D.8 Comm. 2.10.3 SCFs for pipes with internal pressure

The following sections can be used for fatigue assessment of pipelines or cylinders used for transportation of gas subjected to high pressure where low cycle fatigue from loading and unloading are considered.

*Tapered thickness transitions*

For tapered thickness transitions in pipes and cylinders as shown in Figure D-11 the bending stress over the wall thickness at the weld is mainly due to the axial stress in the pipe wall. This means that at thickness transitions the stress concentration factors presented in section 3.3.7 can be used directly together with the nominal stress in the pipe wall for calculation of hot spot stress at the weld. Nominal stress in the pipe wall due to global bending moment can be calculated based on section modulus at the mid wall pipe section.
Figure D-11
Tapered thickness transition in pipe or cylinder

**Thickness transitions with step in thickness**

A transition with a step in thickness from $t_1$ to $t_2$ in a pipe or cylinder as shown in Figure D-12 is considered. It is assumed that the radius of the pipe or cylinder $r > t_1$. The stress due to the end cap pressure is calculated as:

$$\sigma_a = \frac{p r}{2 t_1} \quad \text{(D.8-1)}$$

The total stress at the inner side and the outer side is calculated as:

$$\sigma_i = \sigma_a \pm \sigma_b \quad \text{(D.8-2)}$$

This equation can also be written as:

$$\sigma_i = \sigma_a \left(1 \pm \frac{\sigma_b}{\sigma_a}\right) = \sigma_a \text{SCF} \quad \text{(D.8-3)}$$

where the stress concentration factor for the inner side is:

$$\text{SCF} = 1 + \frac{2 - \nu}{\gamma} \sqrt{\frac{3}{1 - \nu^2}} \left(1 - \frac{t_1}{t_2}\right) \quad \text{(D.8-4)}$$

and the stress concentration factor for the outer side of the pipe is:

$$\text{SCF} = 1 - \frac{2 - \nu}{\gamma} \sqrt{\frac{3}{1 - \nu^2}} \left(1 - \frac{t_1}{t_2}\right) \quad \text{(D.8-5)}$$

The $\gamma$ is defined as:

$$\gamma = \frac{2\left(t_{1.25}^2 + t_2^{2.5}\right)}{t_2^{2.5} - t_2^{0.5} t_1^1} \left(1 + \frac{t_1}{t_2} \right)^{1.5} + \left(\frac{t_1}{t_2}\right)^2 - 1 \quad \text{(D.8-6)}$$

**Ring stiffeners at supports in storage tanks and at flange connections in risers**

A ring stiffener in a cylinder as shown in Figure D-13 is considered. This applies also to a bolted flange connection that is frequently used in risers for oil and gas production, ref. Figure D-14 where the most critical hot spot is found at point B.

The stress concentration at a ring stiffener is obtained as:

$$\text{SCF} = 1 + \frac{\sqrt{3}(2-\nu)}{\sqrt{1-\nu^2}} \frac{1}{\beta} \quad \text{(D.8-7)}$$

where the plus sign applies to the inner side and minus to the outer side. This stress concentration includes effect from internal pressure and end cap pressure. It is to be used together with the nominal stress acting in the axial direction of the pipe wall due to end cap pressure.

$\beta$ is defined as:

$$\beta = 1 + \frac{2 t \sqrt{r t}}{A_r \sqrt{3(1-\nu^2)}} \quad \text{(D.8-8)}$$

With $\nu = 0.3$ for steel the expression for $\beta$ becomes:

$$\beta = 1 + \frac{1.56 t \sqrt{r t}}{A_r} \quad \text{(D.8-9)}$$

and the stress concentration factor for the inner side becomes:

$$\text{SCF} = 1 + \frac{3.087}{\beta} \quad \text{(D.8-10)}$$

and the stress concentration factor for the outer side becomes:

$$\text{SCF} = 1 - \frac{3.087}{\beta} \quad \text{(D.8-11)}$$

Due to the notch of the weld itself the fatigue strength of the weld at the ring stiffener itself becomes less than for the other shell side. As the stress is lesser on the outside than at the inside it is thus recommended to place ring stiffeners on the outside of a shell structure subjected to internal pressure. This is a different conclusion from that of ring stiffeners in tubular members subjected to pure external axial force, ref. /25/.

Deformed shape

---

Figure D-12
Thickness transition in pipe or cylinder

Figure D-13
Ring stiffener on cylinder with internal pressure
Longitudinal welds with bending stress over the pipe wall resulting from out-of-roundness of fabricated pipes

The out-of-roundness of fabricated pipe elements results in increased stress due to a bending moment over the wall thickness, see Figure D-15. The eccentricity due to out-of-roundness is a function of tension in the hoop direction of the pipe. This eccentricity is reduced as the internal pressure is increased and the hoop tension is increased. Thus the bending stress over the wall thickness is a non-linear function of the internal pressure.

It is assumed that the out-of-roundness results in an eccentricity \( \delta_{OOR} \) without any hoop tension force from internal pressure.

In terms of out of roundness the equation for stress concentration factor can be derived as:

\[
SCF = 1 + \frac{1.5 \delta_{OOR}}{t \lambda l} \tanh (\lambda l)
\]

where the out of roundness is defined as \( \delta_{OOR} = d_{\text{max}} - d_{\text{min}} \), \( l = \pi d/8 \) and \( \lambda \) which is a function of the membrane hoop stress \( \sigma_{mm} \) is defined as follows:

\[
\lambda = \sqrt{\frac{12 \sigma_{mm}}{E t^2}}
\]

Tolerance requirements for pipelines are given in DNV-OS-F101 (2001).

D.9 Comm. 3.3 Stress concentration factors

Reference is made to “An Analytical study of Stress Concentration Effects in Multibrace Joints under Combined Loading”, ref. /9/, for further background on this procedure of calculating a resulting hot spot stress from superposition of stress components.

The formula for SCF at a tubular butt weld can be outlined based on theory for thin walled structures, ref. /25/.

D.10 Comm. 3.3.3 Tubular joints welded from one side

The fatigue design of the root area of tubular joints welded from one side may be considered as follows:

- Lack of penetration is hard to control by non-destructive examination and it is considered more difficult to detect possible defects at a root area of a tubular joint welded from one side, than for a butt weld welded from one side.
- For butt welds welded from one side the joint may be classified as F3. The defect size inherent in this curve is less than 1-2 mm (This defect size may be evaluated by fracture mechanics calculations and the calculated value will depend on plate thickness. A long defect should be considered here with the defect size measured in the thickness direction of the tubular). Defect sizes up to 5 mm may be present without being detected even with a detailed examination of the root of a tubular joint. A factor for reduction of fatigue life due to a possible large root defect in a tubular joint compared to a butt weld may be evaluated based on fracture mechanics analysis.
- The stress field at the root may be derived from a finite element analysis. The crack growth may be assumed to be normal to the direction of the maximum principal stress. The fatigue life is first calculated for an initial defect size corresponding to that of the F3 curve: \( F(\text{Life } a_i = 1 \text{ mm}) \). Then the fatigue life is calculated for an initial defect size corresponding to that of a tubular joint welded from one side: \( F(\text{Life } a_i = 5 \text{ mm}) \). The fatigue life reduction factor, \( R \), is obtained from equation (D.10-1).
- A modified S-N curve below F3 is calculated from equation (D.10-2). An S-N curve corresponding to this log a value (or below) may now be used for fatigue life analysis based on nominal stress at the root as calculated by a detailed finite element analysis.
- Fatigue cracking from the root is harder to discover by in service inspection than crack growth from the toe. Therefore, an additional factor on fatigue life should be considered for crack growth from the root.

\[
R = \frac{F(\text{Life } a_i = 5 \text{ mm})}{F(\text{Life } a_i = 1 \text{ mm})}
\]

\[
\log a = 11.546 + \log (R)
\]

The following simplified approach for fatigue life assessment of the weld root may be performed as an alternative procedure:

- As noted above an additional factor on fatigue life should be considered for crack growth from the root.
- Normally the stress on the outside of the brace at the hot spot is larger than at the root area. Hence it is considered to be conservative to use the brace SCF for evaluation of fatigue life at the root. As an approximation the SCF for the inside can be calculated as

\[
SCF_{\text{inside}} = SCF_{\text{brace}} - 2.0
\]

- The fatigue life for the root may now be calculated using the W3 curve.

This procedure is applicable for simple tubular joints only.

D.11 Comm. 4.1 The application of the effective notch stress method for fatigue assessment of structural details

General

Effective notch stress is the total stress at the root of a notch, obtained assuming linear-elastic material behaviour. To take account of statistical nature and scatter of weld shape parame-
The method is restricted to welded joints which are expected to fail from the weld toe or weld root. Other causes of fatigue failure, e.g. from surface roughness or embedded defects, are not covered. Also it is not applicable where considerable stress components parallel to the weld or parallel to the root gap exist.

The method is well suited to the comparison of alternative geometries. Unless otherwise specified, flank angles of 30° for fillet welds are suggested.

The method is limited to thicknesses \( t \geq 5 \text{ mm} \). For smaller wall thicknesses, the method has not been verified.

In cases where a mean geometrical notch root radius can be defined, e.g. after certain post weld improvement procedures such as grinding, the actual geometrical radius may be used in the effective notch stress analysis. Then the calculated notch stress should be entered into a relevant S-N curve. Reference is made to Table A-5 in Appendix A for potential fatigue crack growth from area at welded regions.

Calculation of Effective Notch Stress

Effective notch stresses or notch stress concentration factors can be calculated by parametric formulae, taken from diagrams or calculated from finite element analysis. The effective notch radius is introduced such that the tip of the radius touches the root of the real notch, e.g. the end of an unwelded root gap.

Calculation of effective notch stress by the finite element method requires that a fine element mesh is used around the notch region. The effective notch stress to be used together with the recommended S-N curve is the maximum calculated surface stress in the notch. This maximum surface stress may be obtained directly from the nodal stress calculated at the surface or from extrapolation of element stresses to the surface. In some finite element programs it may also be efficient to add bar elements with a small area (negligible area) along the notch surface. Then the surface stress is finally derived as force in the bar divided by area.

The requirement to mesh size is depending on elements used. If elements with quadratic displacement functions are used, a minimum of 4 elements should be used along a quarter of the circle circumference. If simpler elements are used the mesh refinement should be improved correspondingly. The mesh should be made with regular elements without transition to reduced refinement within the first three element layers from the notch surface. An element shape that is close to “quadratic” is preferred.

In case of uncertainty about elements ability to provide reliable surface stress it is recommended to perform a validation of the methodology against a well known case.

Notch Stress S-N Curves

The calculated notch stress should be linked to a notch stress S-N curve for fatigue design as described in Table D-6. The S-N curves are presented as mean minus two standard deviations in logarithmic S-N format.

The thickness effect is assumed accounted for in the calculated notch stress. Thus a further reduction of fatigue capacity for larger thicknesses is not required.

The S-N curve is presented on the standard form

\[
\log N = \log \sigma - m \log a
\]

(D.11-1)

where

\[ a = \text{intercept of the design S-N curve with the log N axis} \]

\[ m = \text{negative inverse slope of the S-N curve} \]

Validation of Analysis Methodology

The notch stress concept using finite element analysis can be validated against a well tested detail that also can be assessed based on nominal stress approach.

A cruciform joint may be selected for analysis as shown in Figure D-17 and Figure D-18.

The F curve may be used for fatigue assessment of the weld toe using the nominal stress approach.

Then a target notch stress at the weld root is obtained as 3.17 times the nominal stress in the plate.

A fillet welded cruciform joint may be selected for analysis as shown in Figure D-19 and Figure D-20. Then the W3 curve may be used for fatigue assessment of the weld root using the nominal stress approach. The nominal stress in the weld is derived as:

\[
\sigma_{\text{w}} = \sigma_{\text{Nominal}} \frac{t}{2a}
\]

(D.11-2)

where

\[ t = \text{thickness of member} \]

\[ a = \text{throat thickness} \]

Then a target notch stress in the weld root is obtained as 6.25 times the nominal stress in the fillet weld.

If the calculated stress from validation analyses is far from the target values, it is recommended to consider the accuracy of the methodology used such as type of element in relation to mesh refinement and read out of notch surface stress.

The toe of the same detail would be classified as F3. This result in a target notch stresses 3.57 times the nominal stress.

D.12 Comm. 4.3.8 Verification of analysis methodology for FE hot spot stress analysis

Specimens for verification of analysis methodology are shown in Figure D-21 - Figure D-26.

The hot spot stress analysis methodology may be verified based on analysis of these details with derived target hot spot stress.

Loading on the specimens for calculation of hot spot stress is shown in Table D-7.

The target hot spot stresses for the specified load cases are listed in Table D-8.

A correction factor to be applied to the analyses may be established if the calculated hot spot stress in general is different from the target hot spot stress. This correction factor is obtained as

\[ f = \frac{\sigma_{\text{Hot spot Target}}}{\sigma_{\text{Hot spot Calculated}}} \]  

(D.12-1)

D.13 Comm. 5 Simplified fatigue analysis

Weibull distributed Stress Range and Bi-linear S-N curves

When a bi-linear or two-slope S-N curve is used, the fatigue damage expression is given by

\[
D = v_0 T_d \left[ \frac{q^m}{\alpha_1} \left( 1 + \frac{m_1}{h} \left( \frac{S}{q} \right)^h \right) \right] \leq \eta \quad \text{(D.13-1)}
\]

where

- \( S_1 \) = Stress range for which change of slope of S-N curve occur
- \( \alpha_1, m_1 \) = S-N fatigue parameters for \( N < 10^7 \) cycles (air condition)
- \( \alpha_2, m_2 \) = S-N fatigue parameters for \( N > 10^7 \) cycles (air condition)
- \( \gamma() \) = Incomplete Gamma function, to be found in standard tables
- \( \Gamma() \) = Complementary Incomplete Gamma function, to be found in standard tables

For definitions and symbols see also sections 1.4, 1.5 and 5.1.

Alternatively the damage may be calculated by a direct integration of damage below each part of the bilinear S-N curves:

\[
D = \int_0^{S} v_0 T_d f(S, \Delta \sigma_0, h) \frac{\Delta S}{N_2(S)} \, dS + \int_{S_1}^{S} v_0 T_d f(S, \Delta \sigma_0, h) \frac{\Delta S}{N_1(S)} \, dS \quad \text{(D.13-2)}
\]

where the density Weibull function is given by

\[
f(S, \Delta \sigma_0, h) = h \frac{S^{h-1}}{q(\Delta \sigma_0, h)^h} \exp \left( -\frac{S}{q(\Delta \sigma_0, h)} \right)^h \quad \text{(D.13-3)}
\]

The left part of S-N curve is described by notation 1, while the right part is described by notation 2.

**Short term Rayleigh distribution and linear S-N curve**

When the long term stress range distribution is defined through a short term Rayleigh distribution within each short term period for the different loading conditions, and a one-slope S-N curve is used, the fatigue criterion reads,

\[
D = \frac{v_0 T_d}{\alpha_1} \Gamma(1 + \frac{m}{2}) \cdot \sum_{i=1,j=1}^{\text{all loading states}} r_{ij} (2 \sqrt{2 m_{ij}})^m \leq \eta \quad \text{(D.13-6)}
\]

where

- \( r_{ij} \) = the relative number of stress cycles in short-term condition \( i,j \)
- \( v_0 \) = long-term average zero-up-crossing-frequency (Hz)
- \( m_{ij} \) = zero spectral moment of stress response process

The Gamma function, \( \Gamma(1 + \frac{m}{2}) \) is equal to 1.33 for \( m = 3.0 \).
Short term Rayleigh distribution and bi linear S-N curve

When a bi-linear or two-slope S-N curve is applied, the fatigue damage expression is given as,

\[
D = v_0 T_d \sum_{i=1}^{all} \sum_{j=1}^{all seastates} r_{ij} \left[ \left( \frac{2m_{0ij}}{a_1} \right)^m \Gamma \left( 1 + \frac{m_1}{2} \left( \frac{S_0}{2m_{0ij}} \right) \right) \right]^2 + \left( \frac{2m_{0ij}}{a_2} \right)^m \Gamma \left( 1 + \frac{m_2}{2} \left( \frac{S_0}{2m_{0ij}} \right) \right) \right]^2 \text{(D.13-7)}
\]

Example Fatigue analysis of a drum

A drum used for transportation of equipment is assessed with respect to fatigue. Reference is made to Figure D-27. The maximum allowable tension force in the wire on the drum is to be determined. There are three different spaces for wire on the drum, separated by external ring stiffeners 200 × 20 mm. The ring stiffeners are welded to the drum by double sided fillet welds. The highest bending stress in the drum occurs when the wire is at the centre of the drum. Then the reaction force at each support becomes equal P/2 and the maximum bending moment at the highest stressed ring stiffener is Pa/2. When the drum is rotated 180 degrees the bending moment at the same position is reversed and the range in bending moment is derived as

\[
\Delta M = Pa \text{ (D.13-8)}
\]

The section modulus for the drum is calculated as

\[
W = \frac{\pi}{32} (D^4 - (D - 2t)^2) \cdot \frac{1}{D} \text{ (D.13-9)}
\]

where D = diameter = 600 mm and t = thickness = 20 mm. Then W = 5114·10³ mm³.

For the outside of the drum a stress concentration factor is calculated from section 3.3.8

\[
\alpha = 1 + 1.56\sqrt{\frac{r}{A_r}} = 1 + 1.56 \cdot 20 \sqrt{\frac{300}{20}} = 1.60 \text{ (D.13-10)}
\]

\[
SCF = 1 + \frac{0.54}{\alpha} = 1 + \frac{0.54}{1.60} = 1.34 \text{ (D.13-11)}
\]

The nominal stress at the outside of the drum at the considered ring stiffener is obtained as:

\[
\Delta \sigma = \frac{\Delta M}{W} \cdot SCF \cong \frac{Pa}{W} \cdot SCF \text{ (D.13-12)}
\]

Then the maximum tension force is derived as

\[
P = \frac{\Delta \sigma \text{ allowable}}{a \cdot SCF} = \frac{37.13 \cdot 5114 \cdot 10^3}{1200 \cdot 1.34} = 118.1 \text{ kN} \text{ (D.13-14)}
\]

Comm. 7 Improvement of fatigue life by fabrication

Reference is made to “Recommendations on Post weld Improvement of Steel And Aluminium Structures”, ref. /16/, for effect of weld improvements on fatigue life. Reference is also made to “API Provisions for SCF, S-N, and Size-Profile Effects”, ref. /22/, for effect of weld profiling on thickness effect. Reference is made to “Fatigue of Welded Joints Peened Underwater”, ref. /13/, for fatigue of welded joints peened underwater.

D.14 Comm. 2.10.1 Stresses at girth welds in pipes and S-N data

When pipes are subjected to a global bending moment only, the stress on the inside is lower than that of the stress on the outside as shown in Figure D-28. For a pipe with diameter 772 mm and thickness 36 mm the ratio between the stress on the inside and the outside is 0.91.

It should be noted that the local bending stress due to thickness transition and fabrication tolerances is due to the membrane stress over the thickness. This stress is denoted \( \sigma_{\text{thick}} \) in Figure D-28 and this stress is to be used together with equation (2.10.1) for derivation of local bending stress.

The resulting stress at welded connections can be calculated as a sum of the stress from global bending and that from local bending on inside and outside as relevant.

The local bending moment at a distance \( x \) from a weld with an eccentricity can be calculated based on shell theory as

\[
M(x) = M_0 e^{-\xi} \cos \xi \text{ D.14-1}
\]
where the eccentricity moment $M_0$ is derived from as

$$M_0 = \frac{\delta}{2}\sigma_f t$$  \hspace{1cm} \text{(D.14-2)}

where

- $\delta$ = shift in neutral axis due to change in thickness and fabrication tolerance,
- $\sigma_f$ = membrane axial stress in the tubular,
- $t$ = thickness of pipe.

A reduced co-ordinate is defined as

$$\xi = \frac{x}{l_e}$$  \hspace{1cm} \text{(D.14-3)}

where the elastic length is calculated as

$$l_e = \sqrt{\frac{Ft}{3(1-\nu^2)}}$$  \hspace{1cm} \text{(D.14-4)}

where

- $r$ = radius to mid surface of the pipe,
- $t$ = thickness of the pipe,
- $\nu$ = Poisson’s ratio.

The results from this analytical approach have been compared with results from axisymmetric finite element analysis in Figure D-29.

The presented equations can be used to design connections with built in eccentricity to decrease the stress at the root that has a lower S-N curve than at the weld cap (toe). This will, however, increases the stress at the weld toe and this may require weld improvement at the weld toe. The principle of purpose made eccentricity can be used in special situations where a long fatigue life is required such as at long free spanning pipelines, ref. also OMAE2010-20649.
